# ACKNOWLEDGMENTS

I had the good fortune to develop and grow, both scientifically and personally, in the Perioperative Patient Safety group. I would like to thank Prof. Susan Treves for having patience and understanding in sharing her knowledge and experience with me. She gave a support and constructive criticism whenever it was needed and somehow always found a good way to inspire and motivate us. I would also like to thank Prof. Francesco Zorzato for his precise and insightful guidance through my scientific journey.

Special thanks to all members of the lab which contributed in different ways to finalize my work here, without them things would be much less colorful. I would like to thank Prof. Albert Urwyler and Prof. Thierry Girard for their support.

I thank to Prof. Jean Pieters, Prof. Christoph Handschin and Prof. Markus Rüegg, who accepted to be members of my PhD committee.

And finally, I would like to thank my family for their extraordinary support, love and faith in me, which gave me the necessary strength and power to overcome all difficulties and to enjoy this journey.

# ABSTRACT

Excitation-contraction coupling (ECC) is the physiological mechanism whereby an electrical signal detected by the dihydropyridine receptor, is translated into an increase in  $[Ca^{2+}]$ , by activating ryanodine receptors. Mutations in *RYR1*, the gene encoding the ryanodine receptor 1, are the underlying cause of several congenital myopathies including Central core disease, Multiminicore disease, some forms of Centronuclear myopathy and Congenital fiber type disproportion. Patients with recessive but not dominant *RYR1* mutations show a significant reduction of ryanodine receptor protein in muscle biopsies as well as ophthalmoplegia or involvement of the extraocular muscles (EOM). This specific involvement indicates that this group of muscles may express different proteins involved in excitation-contraction coupling compared to limb muscles. The focus of this thesis is the characterization of the excitation-contraction coupling toolkit of human EOM. The main goal was to identify differences or similarities with other skeletal muscles in the context of the previously mentioned diseases which affect skeletal muscles. My results indicate that the transcripts of the main genes involved in skeletal excitation-contraction coupling are downregulated, while at the same time, we report increased expression of the ryanodine receptor 3, cardiac calsequestrin and alfa 1 subunit of the cardiac dihydropyridine receptor. In addition, the finding of increase in excitation-coupled calcium entry in the EOM compared to leg muscles (LM) completes the picture of the EOM muscles as a specific muscle group with a unique mode of calcium handling and their selective involvement in neuromuscular disorders.

Facial weakness and ptosis have also been described in patients with mutations in *RYR1*. Having this in mind, we were interested in investigating the relation between the facial muscle orbicularis oculi (OO), EOM and LM and the excitation-contraction coupling toolkit in human biopsies and myotubes derived from individuals which do not have any known neuromuscular disorder. According to our results, OO show more similarities to leg muscles than to EOM. In addition, we found high expression levels of dystrophin and utrophin and this is significant from the perspective of Duchenne muscular dystrophy (DMD). In fact in this condition EOM are spared from pathology and the same is true in mdx (dystrophin deficient) mouse models. In mdx

mice it is believed that utrophin compensates for the lack of dystrophin. Our findings that *UTRN* is expressed at higher level in OO compared to LM in normal conditions strongly support this theory of a compensatory effect by utrophin when dystrophin is missing.

Further investigations in my thesis focus on two isoforms of the ryanodine receptor, namely RyR1 and RyR3. Ryanodine receptor 1 plays a crucial role in the process of excitation-contraction coupling in skeletal muscle. According to our study on normal human EOM, the expression of this receptor is decreased compared to its expression levels in human leg muscles, however the expression level of RyR3 is significantly increased. Because of these latter results, we reasoned that the reported behavioral impairment reported in *RYR3* KO mice, may actually be due to alterations of EOM function. Our preliminary data show that in fact *RYR3* KO mice exhibit visual impairment as measured using their optokinetic reflex. We are currently investigating the role of RyR3 in EOM calcium homeostasis.

Taken all together, this thesis shows that different involvement of EOM and OO in neuromuscular disorders is due to their different excitation contraction coupling toolkit component. Furthermore, EOMs exhibit characteristics that deserve further attention as further investigations may lead to the discovery of protective mechanisms in neuromuscular disorders with potential therapeutic benefit.

# LIST OF ABBREVIATIONS

2-APB	2-aminoethyl diphenylborate
4-CmC	4-chloro-m-cresol
ACTA1	$\alpha$ -skeletal actin 1
AP	Action potential
ARVD2	Arrhythmogenic right ventricular dysplasia type 2
BIN1	Bridging Integrator 1
CaM	Calmodulin
CaMKII	Ca <sup>2+</sup> /calmodulin dependent protein kinase II
Ca <sub>v</sub>	Voltage-gated calcium channel
CCD	Central core disease
CFTD	Congenital fiber type disproportion
CICR	Ca <sup>2+</sup> induced Ca <sup>2+</sup> release
CNM	Centronuclear myopathy
CNS	Central nervous system
COX	Cytochrome oxidase
CPVT	Catecholaminergic polymorphic ventricular tachycardia
CSQ	Calsequestrin
DHPR	Dihydropyridine receptor
DNM2	Dynamin 2
ECC	Excitation-contraction coupling
EOM	Extraocular muscles
FDHM	Full duration at half maximum
FKBP12	FK506-binding protein
FWHM	Full width at half maximum
H&E	Haematoxylin and eosin
IVCT	In vitro contracture test
JP45	Junctional SR protein 45
Mg29	Mitsugumin 29
MH	Malignant hyperthermia

MHS	Malignant hyperthermia susceptibility
MIFs	Multiply innervated fibers
MmD	Multi-minicore disease
MTM1	Myotubularin1
MyHC	Myosin heavy chain
NADH-TR	Nicotinamide adenine dinucleotide tetrazolium reductase
NCX	Na <sup>+</sup> /Ca <sup>2+</sup> exchanger
OO	Orbicularis oculi
PDE4D3	cAMP-specific phosphodiesterase type 4
PI3P	Phosphatidylinositol 3-phosphate
Pitx2	Paired-like homeodomain transcription factor 2
PKA	Protein kinase A
PMCA	Plasma membrane Ca <sup>2+</sup> ATPase
PP1	Protein phosphatase 1
PP2A	Protein phosphatase 2
RyR	Ryanodine receptor
SAM	Sterile- $\alpha$ -motif
SARKO	Sarcalumenin knockout
SDH	Succinate dehydrogenase
SEPN1	Selenoprotein N
SERCA	Sarcoendoplasmatic reticulum Ca <sup>2+</sup> transport ATPase
SIFs	Singly innervated fibers
SKF 96356	N,6-dimethyl-1-(2-methylphenyl)-2,3-dihydropyrrolo[3,2-c]quinolin-4-amine
SOCE	Store-operated calcium entry
SR	Sarcoplasmic reticulum
STIM1	Stromal interaction molecule 1
TPM3	Tropomyosin 3
TRDN	Triadin

# CHAPTER 1: INTRODUCTION

## 1.1 Craniofacial muscles

More than 10% of the total number of muscles in the human body are found in the craniofacial region. The craniofacial muscles are involved in a number of crucial non-locomotor activities, and are critical for the most basic functions of life, including vision, taste, chewing and food manipulation, swallowing, respiration, speech, as well as regulating facial expression and controlling facial aperture patency. The biology of these small skeletal muscles is relatively unexplored. According to their developmental origin, they can be divided into extraocular muscles, branchiomeric muscles (facial, masticatory, pharyngeal and laryngeal muscles) and tongue muscles [1]. Their unique embryonic development and the genes that control it together with characteristic features that separate them from the skeletal muscle stereotype have started to be explored only recently [2].

Limb and trunk skeletal muscles are derived from the segmented paraxial mesoderm known as somites [2] while the origin of facial muscles is different and they do not follow the progression from mesoderm to segmented somites. The cranial mesoderm from which craniofacial muscles derive seems to be characterized more by molecular factors than for example, by anatomical ones [3], however, there is little information on the formation of facial muscles. The craniofacial muscles are highly heterogeneous as far as structure, function, anatomy and development are concerned. There are around 60 muscles in the head of vertebrates namely, those surrounding the eye - extraocular muscles (EOM) (derived from prechordal and paraxial mesoderm), those involved in mastication (derived from pharyngeal arch 1) and facial expression (derived from pharyngeal arch 2). The muscles of the 3<sup>rd</sup> pharyngeal arch (also known as branchial arch) control the larynx and pharynx. A number of head muscles (including the hypobranchial, tongue, posterior arch muscles) develop from the somites (Fig.1) [4].

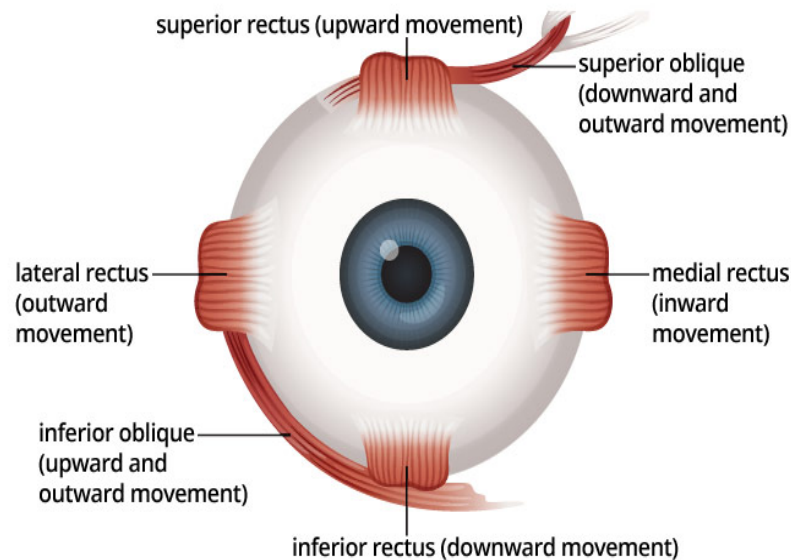

**Figure 1: Development of skeletal muscles.** Skeletal muscles and satellite cells in trunk and limb derive from somites (paraxial mesoderm). Pharyngeal arch (PA) muscles and their associated satellite cells derive from both cranial paraxial mesoderm and splanchnic mesoderm sources. Extraocular muscles derive from prechordal and paraxial mesoderm (somitomes) [4].

### 1.1.1 Human extraocular muscles

Understanding the biology of skeletal muscles, does not necessarily mean understanding and knowing the physiology of extraocular muscles. They are among the fastest and most fatigue resistant muscles, but at the same time the presence of the slow, non-twitch muscles and some cardiac or embryonic skeletal muscle characteristics gives them a special place when it comes to classification [5, 6]. EOM are highly specialized muscles with six fiber types, high-frequency pattern of neuromuscular innervation as well as the singly and multiply innervated fibers which sets them in a distinctive group of muscles compared to the other skeletal muscles [7]. At early stages the development of extraocular muscles is dependent on the expression level of the transcription factor Pitx2. If the expression of Pitx2 is low, the formation of the oblique muscles does not occur, and the rectus muscles that develop are smaller. In case of Pitx2 absence the extraocular muscles do not develop at all [8, 9]. Extraocular muscles derive from prechordal and paraxial mesoderm (somitomes) [4].

There are the six extraocular muscles, which act to turn or rotate an eye about its vertical, horizontal, and antero-posterior axes: superior rectus, inferior rectus, medial rectus, lateral rectus, superior oblique and inferior oblique (Fig. 2).

**Figure 2: Human extraocular muscles.**

(<http://www.allaboutvision.com/conditions/strabismus-surgery.htm>)

The histological structure of eye muscles differs in many aspects from that of other striated muscles. Extraocular muscles contain fibers of varying diameters and in general they are the finest fibers found in any striated muscle. They vary in diameter from 9  $\mu\text{m}$  to 17  $\mu\text{m}$ , with fibers as fine as 3  $\mu\text{m}$ , but these muscles also contain coarse fibers up to 50  $\mu\text{m}$  in width. As far as the literature goes there is no consensus as to whether each EOM fiber runs the entire length of the EOM or not. In general if each muscle would run the entire length, one would expect to find the same number of fibers in sections taken from the anterior, middle, or posterior portion of each EOM. But instead, it has been reported that the number of fibers in the central region of the muscle is higher than in proximal or distal areas [10, 11].

In extraocular muscles two layers can be distinguished: the orbital and global (Fig. 3) [12]. The orbital layer faces the orbital wall while the global layer faces the eyeball and is in part enclosed by the orbital layer. The orbital layer contains small-diameter fibers with many mitochondria and a dense vascular network. The global layer contains larger-diameter fibers with a variable content of mitochondria and fewer vessels.

**Figure 3: Cross section of (a) human and (b) rat ocular medial rectus muscle.** Histochemical staining for succinate dehydrogenase (SDH) exhibits higher oxidative activity in the thinner orbital layer than in the thicker global layer. Human medial rectus muscle is much larger with a broad intermediate layer and a lot of connective tissue separating muscle fascicles. Scale bar 50 $\mu$ m [13].

In human EOM a third layer has been described and named marginal zone, located outside of the orbital layer, with fibers larger than the ones from the orbital layer and with a higher number of the multiply innervated fibers. It covers the whole length of the muscle except the very proximal and distal regions [10].

The EOM function could not be assigned to any particular layer. Predicting the function of any muscle without first establishing the mechanical connections between the fibers would be difficult and challenging. Elastic tissue is unusually abundant in extraocular muscles of adults and the elastic fibers are thick and arranged parallel to the muscle fibers. These longitudinal fibers are interconnected by transverse elastic fibers that form a very dense network around the muscle fibers. Recent anatomic studies have demonstrated that each rectus EOM passes through a pulley consisting of a surrounding ring or sleeve of collagen, located near the globe equator in Tenon's capsule (Fig. 4). Pulleys are connected to the orbital wall, adjacent EOMs, and

equatorial Tenon's capsule by bands containing collagen, elastin, and smooth muscles [14, 15]. Spindles are located in the peripheral layers of small diameter fibers and near their tendon. In general there are around 50 spindles in each EOM.

**Figure 4: A pulley, that is supported by the orbital layer of the muscle guides the global layer that inserts in the globe.** ([http://www.efelder.de/eye\\_muscle\\_morphology.html](http://www.efelder.de/eye_muscle_morphology.html))

## **Myosin Heavy Chain expression in human EOM**

The highly specialized function of EOMs, that is to move the eyeball, is reflected in the specific Myosin Heavy Chain (MyHC) content and the complexity of fiber types. The MyHC expression pattern in adult EOM is different than that in adult skeletal muscle; in fact in single EOM fibers, developmental MyHC isoforms (neonatal and embryonic), are co-expressed together with adult MyHC isoforms, while normal adult skeletal muscle fibers only express adult MyHC isoforms [16-18]. The EOM specific MyHC13 isoform is also present in EOM [16] but additionally variations in MyHC isoform expression along single muscle fibers have been described [19]. Adult rabbit EOM also contain the cardiac MyHC isoforms [20].

In a study on the MyHC composition in human EOM, six isoforms were detected: MyHCemb/IIx, MyHCIIa, MyHCeom, MyHCI, and 2 unidentified forms. MyHCIIb was not detected. In the same study it was also shown that MyHC isoforms have a different pattern of expression in the human superior oblique muscle compared to the rectus muscles and inferior oblique muscles [21].

## **EOM fiber types**

Human skeletal muscle fibers are usually divided into three major types based on their physiological, biochemical and histochemical characteristics: 1) slow twitch, fatigue resistant (type I fibers), 2) fast-twitch, fatigue resistant (type IIA fibers) and 3) fast-twitch fatigable (type IIB fibers - based on ATPase staining, IIX based on MyHC composition) [22]. EOM fiber classification can differ significantly based on the criteria taken for the fiber type characterization. The initial classification was based on the histological features and they were called “Felderstruktur” or “Fibrillenstruktur” [23]. The slow fibers of the Felderstruktur type were described as clumped together in a more or less afibrillar appearing mass of myofilaments with large, partially fused fibers in sparse sarcoplasm with poorly developed sarcoplasmic reticulum. The Fibrillenstruktur type of the fast fiber system were characterized anatomically by small, well defined fibers, each surrounded by abundant sarcoplasm and having an even, punctate appearance when observed under the light microscope. Classification in “coarse”, “granular” and “fine” came with the characterization of the amount and distribution of mitochondria [24]. This was followed by a more comprehensive description of rat EOM fiber types which included, location, diameter, innervation pattern, histochemical features and ultrastructure. Based on these criteria, six fiber types could be identified [25]. Later studies in different mammals confirmed the presence of the six different fiber types in EOM.

In human EOM fiber type classification, mitochondrial content was used to distinguish the different fiber types [26]. Studies based on ATPase staining together with the glycolytic and oxidative enzyme activity and MyHC isoform expression confirmed the higher complexity and fiber type diversity in EOM [27].

It is now generally agreed that in humans and higher mammals there are six fiber types in the EOMs and these can be classified on the basis of their location, innervation and color into: 1) orbital multiply innervated, 2) orbital singly innervated, 3) global multiply innervated, 4) global red singly innervated, 5) global intermediate singly innervated and 6) global pale singly innervated fibers [12]. None of the previously mentioned methods independently covers the full extent of differences present in EOM fibers [10].

## **Innervation of EOM**

EOMs are innervated by lower motor neurons that form three cranial nerves: the abducens, the trochlear, and the oculomotor [28]. Compared to other skeletal muscles they are highly innervated and exist as both singly innervated fibers (SIFs) and multiply innervated fibers (MIFs), whereas trunk and limb skeletal muscles contain exclusively singly innervated fibers [29].

The motor neurons are very thick, due to the large number of fibers they contain. The ratio of nerve fibers to muscle fibers is nearly 1:12 in extraocular muscles, whereas in skeletal muscles it may be as high as 1:125. The abundance of nerve fibers has led to the conclusion that the all-or-none law could apply to eye muscles. According to this general principle, individual muscle fibers always respond with a maximum contraction to every stimulus that exceeds the threshold potential, otherwise there is no response. The amount of contraction of a muscle depends on the number of fibers taking part in a contraction [30].

## **Physiology of EOM**

The physiological and pharmacological properties of extraocular muscles correspond to many unusual histological features. In an electromyographic study it was shown that responses of human extraocular muscles are considerably lower in amplitude (20 to 150  $\mu\text{V}$ ), of much shorter duration (1 and 2 ms), and much higher in frequency (up to 150 cps (contractions per second)), than those of peripheral skeletal muscles, in which the amplitude is 100 to 3000  $\mu\text{V}$ , the duration, 5 to 10 ms and the frequency only up to 50 cps [30].

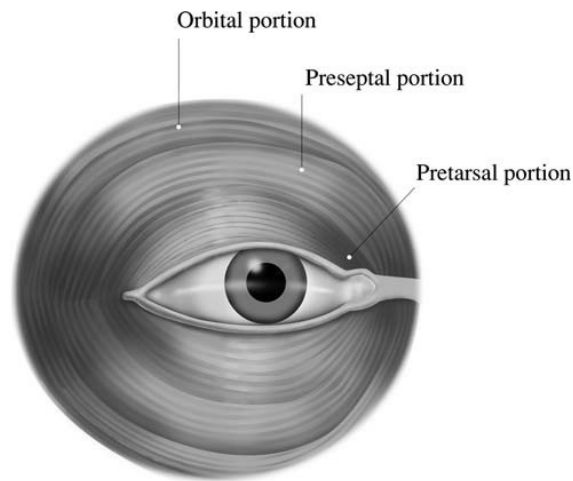

Extraocular muscles contract much more quickly than other voluntary muscles. As a measure of comparison, contraction times on cat muscles were: soleus muscle, 100 ms; gastrocnemius muscle, 40 ms; and medial rectus muscle, 8 ms. [31, 32]. The great speed of contraction of extraocular muscles is in keeping with the requirements of saccadic eye movements and with what is known of the structure and innervation of extraocular muscles.

Since the discovery that a dual motor system of slow and fast fibers exists in extraocular muscles, experiments have shown that acetylcholine, choline, and nicotine cause slow and tonic contraction of slow fibers, whereas fast fibers respond with a fast twitch. The response of extraocular muscles to neuromuscular blocking agents is of clinical interest, since these drugs are often used during general anesthesia [30].

### 1.1.2 Orbicularis oculi muscles (OO)

Orbicularis oculi (OO), together with the tarsal plate form the core of the eyelid. These are muscles important for facial expression and are innervated by the facial nerve (VII) [33]. OO are located directly under the surface of the skin around the eyes. Their function is to close the eyelid and to assist in passing and draining tears through the tear draining system. They are composed of three portions: the orbital portion, the palpebral portion and the lacrimal portion (Fig. 5). **The orbital portion** is involved in closing the eyelids firmly and is controlled by voluntary action. Coarse fibers surround the entire orbit. It has two origins: the frontal bone and the maxilla. The insertion circles around the orbit and it contracts to tightly close the eyes. **The palpebral portion** closes the eyelids gently as part of the involuntary or blinking reflex. This portion has three parts: the pretarsal, preseptal and ciliary part. It is made up of fine fibers and originates from the medial palpebral ligament and inserts into the zygomatic bone, specifically at the lateral palpebral ligament. **The lacrimal portion** compresses the lacrimal sac, which receives tears from the lacrimal ducts and transfers them into the nasolacrimal duct. Its origin is the lacrimal bone and its insertion is the lateral palpebral raphe. It has its own ciliary bundle [34].

**Figure 5: The three anatomical portions of human orbicularis oculi muscle [35].**

The anatomy of the orbicularis oculi muscle is important in treating a number of conditions that require corrective eyelid surgery. It is also important in the physiology of blinking, corneal wetting, and lacrimal excretion through the lacrimal pump. The fibers in orbicularis oculi muscles have the smallest diameter of any skeletal muscle. There are differences in fiber cross-section and fiber type composition between different portions of the muscle. The pretarsal region has the smallest fiber cross-sectional areas and this region is composed almost entirely of type II fibers. The number of type I fibers increases when moving away from the eyelid margin towards the periphery, but the muscle in general is 80-90% composed of type II fibers [33].

The OO differ from both limb and extraocular muscles (EOM) in their histology and histochemistry. In OO there is a predominance of type IIB fibers, the fast fibers which are not able to sustain contraction for long periods of time due to fatigue and are ideally suited for blinking. Sustained squeezing of the eyelids can occur due to type IIA fibers which are fast but fatigue resistant. During sleep the OO are at rest, and the lid position is determined by the equilibrium between the state of relaxation of the levator muscles and OO [36].

The OO differ from some other facial muscles with regard to the ratio of type II muscle fiber subtypes. It was reported that type IIB fibers are present in the levator labii and OO. Type II fibers are more numerous in each of the facial muscles than in limb muscles [36].

Normal OO possess some features which, when present in limb or trunk muscles, would be considered consistent with a chronic myopathy or dystrophy. These include marked fiber size variation, rounded fiber shape, structural alterations such as lobulation and irregular coarseness of stainable sarcoplasmic network, absence of checkerboard pattern of fiber-type distribution, and an increase in endomysial and perimysial connective tissue. Although the OO do not appear to possess many of the characteristics of EOM, they are similar to them and to other facial muscles and can be placed somewhere between them with respect to histologic and histochemical parameters [36].

## **1.2 Excitation-contraction coupling (ECC)**

### **1.2.1 ECC in skeletal muscle**

Excitation-contraction coupling is the mechanism which involves a specific sequence of events starting from initiation and propagation of the action potential (AP) along the plasma membrane (sarcolemma), radial spreading of the potential along the transverse T-tubule system, DHPR (L-type  $\text{Ca}^{2+}$  channel)-mediated detection of changes in membrane potential, allosteric interaction of DHPR with RyR, release of  $\text{Ca}^{2+}$  from the SR and transient increase in cytoplasm  $\text{Ca}^{2+}$  concentration, transient activation of the cytoplasmic  $\text{Ca}^{2+}$  buffering system and contractile machinery, followed by a decrease of the cytoplasmic  $\text{Ca}^{2+}$  levels by the reuptake by SR through sarcoendoplasmic reticulum  $\text{Ca}^{2+}$  transport ATPase (SERCA) and to a lesser extent by its transport by the  $\text{Na}^+/\text{Ca}^{2+}$  exchanger (NCX) and plasma membrane  $\text{Ca}^{2+}$  ATPase (PMCA) [37-39].

The release of divalent ions from the SR requires the expression of both the skeletal muscle L-type  $\text{Ca}^{2+}$  channel DHPR and the RyR1 since depolarization-induced  $\text{Ca}^{2+}$  entry is absent in myotubes lacking either the DHPR  $\alpha_{1S}$  subunit (*dysgenic*) or RyR1 (*dyspedic*), respectively [40]. Skeletal ECC is practically exclusive for RyR1, since RyR2 and RyR3 are not able to recover the skeletal type of ECC when expressed in RyR1 deficient skeletal muscle cells [41].

T-tubules are invaginations of the plasma membrane that transversely expand into the muscle fiber allowing membrane depolarization to reach deep into the fiber to form the triad, i.e a region, where one T-tubule is surrounded by two terminal cisternae of the SR with their so called junctional regions [42, 43]. In the junctional region RyR1 face DHPR receptors located on the membrane of the T-tubule forming tetrads (Fig. 6 and 7) [44, 45].

**Figure 6: T-tubule DHPR and RyR localization.** (<https://www.premedhq.com/t-tubule-system>)

Many proteins are engaged in the process of the ECC among them, calsequestrin, triadin, junctin, junctophilin, FKBP12, mitsugumin, sarcalumenin and JP45. Nevertheless RyR1s and DHPRs are considered the main players since in their absence no ECC occurs.

The DHPR is the physiological regulator of the RyR1 during ECC, but it is by no means the only regulator of RyR1 channel activity. Like RyR2 channels present in the heart, in the absence of the DHPR, RyR1 channels can be activated by cytosolic  $Ca^{2+}$  via a process called  $Ca^{2+}$  induced  $Ca^{2+}$  release (CICR). This is important because more than half of the RyR1 channels are not coupled to DHPRs [46, 47] and it is generally believed that CICR acts to amplify the signal that is generated by the DHPR-RyR1 interaction. Interestingly, the presence of “coupled” and “uncoupled” RyR1 channels indicates that RyR1 function can be heterogeneous. The amount of uncoupled RyR1 channels is not the same in all skeletal muscles. Slow-twitch skeletal

muscles may have three or more uncoupled RyR1 channels for each DHPR-linked RyR1 channel [46, 47]. Slow-twitch muscles have a slower rate of ECC and the number of uncoupled RyR1 may be partially responsible for this and in line with the fact that they have a more pronounced CICR [48, 49].

**Figure 7: Structure of Calcium Release Units in adult skeletal muscle fibers.** In adult skeletal muscle, junctions are mostly triads: two SR elements coupled to a central T-tubule. **(A)** A triad from the toadfish swim bladder muscle in thin section EM: the cytoplasmic domains of RyRs, or feet, and calsequestrin are well visible. **(B)** A tri-dimensional reconstruction of a skeletal muscle triad showing the ultrastructural localization of RyRs, DHPRs, Calsequestrin, Triadin, Junctin, and  $\text{Ca}^{2+}/\text{Mg}^{2+}$  ATPases. The DHPRs are intramembrane proteins that are not visible in thin section EM but can be visualized by freeze fracture replicas of T tubules (panel C). **(C)** DHPRs in skeletal muscle DHPRs form tetrads, group of four receptors (see enlarged detail), that are linked to subunit of alternate RyRs (smodels in B and E). **(D)** In sections parallel to the junctional plane, feet arrays are clearly visible (toadfish swimbladder muscle): feet touch each other close to the corner of the molecule (see enlarged detail). **(E)** Model that summarizes finding of panels C and D: RyRs form two (rarely three) rows and DHPRs form tetrads that are associated with alternate RyRs (RyRs in blue; DHPRs in purple; T-tubule in green). (EM courtesy of Clara Franzini-Armstrong; 3D reconstruction of RyRs courtesy of T. Wagenknecht) [50].

### 1.2.2 ECC in cardiac muscle

In cardiac muscle, ECC is dependent on a phenomenon called calcium-induced calcium release (CICR). Calcium induced calcium release is, as its name indicates, a process whereby an increase in  $\text{Ca}^{2+}$  concentration at the cytoplasmic surface of the intracellular  $\text{Ca}^{2+}$  store induces a release of  $\text{Ca}^{2+}$ . This process involves the conduction of calcium ions into the cell initiating further release of ions into the cytoplasm. This influx of  $\text{Ca}^{2+}$  occurs through the cardiac isoform of the alpha 1 subunit of the DHPR [51] and is initiated by an action potential which triggers the  $\text{Ca}^{2+}$  release from the SR which leads to cardiac contraction. The initial trigger is generated by depolarization of the plasma membrane, which allows  $\text{Ca}^{2+}$  entry through the L-type  $\text{Ca}^{2+}$  channels located on the transverse T-tubules. This influx of  $\text{Ca}^{2+}$  initiates a large intracellular  $\text{Ca}^{2+}$  release from the SR via RyR2s, which elevates cytosolic  $\text{Ca}^{2+}$  concentrations from 100 nM during diastole to about 1  $\mu\text{M}$  during systole, and this  $\text{Ca}^{2+}$  elevation activates cardiac contraction.

There is about one DHPR for every 5 to 10 RyR2 channels in heart muscle and there is no finely defined alignment between these two proteins, as is the case in skeletal muscles (Fig. 8) [50, 52]. Long cardiac action potentials of about ~100ms give enough time for the DHPR to open and facilitate the influx of  $\text{Ca}^{2+}$  which will result in activation of the underlying RyR2 channels through the previously mentioned CICR mechanism. The fact that  $\text{Ca}^{2+}$  is the mediator of ECC in the heart makes signal transduction between cardiac DHPR and RyR2 much slower compared to that occurring between the skeletal isoforms of these proteins. This however, leaves more space for a higher level of regulation of DHPR-RyR2 interaction in cardiac muscle. [53, 54].

Procaine and tetracaine inhibit CICR and are used for investigating the physiology of this process. Ruthenium and high concentrations of ryanodine are inhibitors of RyR channels and also block CICR. In mature skeletal muscles CICR doesn't play a primary role so its exact role remains elusive.

**Figure 8: Structure of calcium release units in cardiac myocytes.** Junctions in cardiac muscle cells are usually in the form of dyads or peripheral coupling formed by SR and either a T-tubule or the sarcolemma. **(A)** DHPRs in cardiac junctions do not form tetrads, but they are randomly arranged in exterior membrane domains that face arrays of feet. This observation implicates that DHPRs are not directly linked to RyRs in the heart. **(B)** RyRs, pointed by the arrow, usually form large clusters instead of the two rows described for skeletal muscle junctions. **(C)** Tri-dimensional reconstruction of a cardiac muscle dyad/peripheral coupling showing the ultrastructural localization of RyRs, DHPRs, Calsequestrin, Triadin, and Junctin. Bar, 0.1  $\mu$ m (3D reconstruction of RyRs courtesy of T. Wagenknecht) [50].

## 1.2.3 Components of ECC

### Ryanodine receptors (RyRs)

As mentioned in the previous sections,  $\text{Ca}^{2+}$  is an essential component for the process of excitation-contraction coupling. The biggest store of  $\text{Ca}^{2+}$  in striated muscles is the sarcoplasmic reticulum (SR). The major channels located on the membrane of the SR which are responsible for  $\text{Ca}^{2+}$  release are ryanodine receptors (RyRs) while inositol 1,4,5-triphosphate receptors ( $\text{IP}_3\text{Rs}$ ) for  $\text{Ca}^{2+}$  channels are located on the endoplasmic reticulum and are not involved in ECC [55, 56]. There are three isoforms of RyR receptors in vertebrates (RyR1, RyR2 and RyR3) which are encoded by three different genes and which vary in their tissue distribution. RyR1 is predominantly expressed in skeletal muscle and to a minor extent in some areas of the CNS and in some immune cells; RyR2 is present in the heart and in the cerebellum and RyR3 was first identified in the brain, but later identified in developing tissues, including developing skeletal muscle [57, 58]. The three isoforms share 65% sequence identity, the biggest difference being detected in areas called “divergent regions”; D1 (from residue 4254-4631 in RyR1), D2 (from residue 1342-1403) and D3 (from residue 1872-1923) [58]. The name of the receptor comes from the alkaloid ryanodine isolated from the South American plant *Ryania speciosa*, which in nanomolar concentrations locks the channel in a subconductance state and in concentrations above  $100\mu\text{M}$  induces inhibition of  $\text{Ca}^{2+}$  release [59-62].

Channel activity is modulated in a direct or indirect manner by dihydropyridine receptors (DHPR) and a number of other proteins including protein kinase A, FKBP12 and FKBP12.6, calmodulin, S100,  $\text{Ca}^{2+}$ /calmodulin dependent protein kinase II (CaMKII), calsequestrin (CSQ), triadin, junctin, as well as by ions like  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$  [63-77].

## RyR1

RyR1 is the biggest known ion channel with a homotetrameric structure, each subunit has an apparent molecular mass of ~565 kDa, and is made up of 5038 amino acids in human isoform ASI (-) and 5033 amino acids in isoform ASI (+). *RyR1* was originally cloned and sequenced from skeletal muscle by Takeshima et al. and Zorzato et al. [78, 79]. The gene encoding human *RyR1* is located on chromosome 19q13.2. The C terminal region contains the transmembrane domains and ion conducting pore, while the major part of the protein is the N-terminal cytoplasmic region which contains the domain interacting with the DHPR as well as domains involved in channel modulation [80].

Skeletal muscle is the tissue which is most enriched in RyR1 where it is located in the junctional region of the terminal SR [78, 79, 81] but other tissues including smooth muscle cells, stomach, kidney, thymus, Purkinje cells, adrenal glands, ovaries, and testis, dendritic cells and B-lymphocytes also express this protein but in lower amounts [78, 82-88].

The crystal structure of RyR is not yet fully resolved, but there are several cryo-EM studies which agree on the overall structure of the receptor (Fig. 9) [89-92]. The general structure can be presented as mushroom-like, with a big cap containing about 80% of the total volume located in the cytoplasmic region, facing the transverse tubules and the stalk which goes through the membrane into the SR lumen. The cytoplasmic region is about 270×270×100Å and the trans-membrane region is 120×120×60Å. The cytoplasmic cap is structured, contains many cavities and globular masses which may correspond to individual or groups of folded domains. The globular regions were numbered and are often called “subregions” [93, 94]. Most cryo-EM investigations have been performed on RyR1, there are several on RyR2 and RyR3 but to a lower resolution. In general, the overall structural shape is similar for all three isoforms [95, 96].

**Figure 9: Cryo-EM structures of RyR.** Shown are isocontour maps for cryo-EM reconstructions of RyR at 9.6Å (EMDB accession number 1275) [97]. **(A)** and **(B)** top (from the cytosol facing the ER/SR membrane) and side views of the RyR. The numbers indicate subregions, a nomenclature that has been used extensively in literature.

The number of the transmembrane helices is still under investigation, but the general consensus is that there are six or eight segments per subunit [98]. The inner helices create the pore-forming region. The purified protein can form a planar crystalline structure with a checkerboard pattern in the absence of any other protein [99]. Subregion 6 in the clamp region is responsible for the inter-protein interactions while the clamp region undergoes significant movement during opening and closing of the channel which can be also transmitted to the neighboring RyRs [89, 100]. This feature could be partly responsible for the phenomenon of coupled gating, where opening of one channel can induce opening of the neighboring channels through physical interactions [101].

Lack of *RYR1* in mice results in a lethal phenotype; knockout mice most likely die at birth because of breathing impairment, but they also exhibit skeletal abnormalities such as spinal curvature, arched vertebral column, thin limbs and a thick neck [102].

## RyR2

RyR2 was first identified in cardiac muscle [84]. In humans, the gene encoding *RYR2* is located on chromosome 1q43 and spans 102 exons, *RYR2* is also expressed at high levels in Purkinje cells of the cerebellum and cerebral cortex [103] and to lower levels in the stomach, smooth muscle cells, adrenal glands, ovaries, thymus and lungs [104] [83].

RyR2 is the major SR  $\text{Ca}^{2+}$  release channel involved in cardiac excitation–contraction coupling, the process by which an electric depolarizing impulse is transduced into a cardiac contraction. The amount of released  $\text{Ca}^{2+}$  from the SR via RyR2 in great deal determines the  $\text{Ca}^{2+}$  transient amplitude, which correlates with the strength of systolic contraction [105]. The RyR2 channel consists of 4 pore-forming subunits that interact with numerous accessory proteins such as FKBP12.6, calmodulin, calsequestrin-2, junctin, triadin, and junctophilin-2. Each of these accessory proteins can regulate channel gating [106]. RyR2 is regulated at the post-translational level by S-nitrosylation, oxidation, and protein phosphorylation [107].

Mutations in *RYR2* are associated with catecholaminergic polymorphic ventricular tachycardia (CPVT) and arrhythmogenic right ventricular dysplasia type 2 (ARVD2) [108, 109].

## RyR3

In humans, the *RYR3* gene is encoded by 103 exons and is located on chromosome 15q13.3-14. RyR3 is expressed in hippocampal neurons, thalamus, Purkinje cells, corpus striatum, skeletal muscles with the highest expression in the diaphragm, smooth muscle cells of the coronary vasculature, lung, kidney, ileum, jejunum, spleen, stomach of mouse and aorta, uterus, ureter, urinary bladder, and esophagus of rabbit [58]. RyR3 is usually not the predominant RyR protein and it is often co-expressed with RyR1 or RyR2 in different tissues. In adult diaphragm muscle, RyR3 constitutes 1–4% of the total [<sup>3</sup>H]ryanodine binding sites and the rest is due to RyR1 [110].

In mice, the RyR3 protein can be detected in skeletal muscles from the 18<sup>th</sup> day of the embryonic stage up to 15 days postnatal. Later, during development the levels decrease and almost completely disappear [111]. In *RYR3* KO mice, the isolated neonatal skeletal muscles show decreased tension development after stimulation with caffeine and contractile force after electrical stimulation. ECC is relatively normal in these mice compared to WT. Based on the available data, it seems that RyR3 have a role in both development and contraction of neonatal muscles [112], however, very little is known about its function. In fact, mice lacking RyR1 and RyR2 die early either at birth or during embryonic development [113, 114], while mice lacking RyR3 live normal lives and show no significant changes in muscle function or reproduction. [112, 115]. In toadfish and frog skeletal muscles, RyR3 is localized on the parajunctional membranes, immediately adjacent to the junctional region from [116].

There are strong suggestions that the activation of RyR3 is indirect, since it is not activated by DHPR. It can be assumed that activation of RyR1 by the DHPR occurs first and then activation of RyR3 occurs by CICR which then contributes to the amplification of ECC induced Ca<sup>2+</sup> release. Since parajunctional RyR do not seem to be in close proximity to junctional RyR, then one can exclude the functional interaction of parajunctional RyR3 and junctional RyR1. The most likely possibility is that RyR3 is activated by the Ca<sup>2+</sup> wave coming from the activated RyR1.

## **Regulators of RyR:**

Ca<sup>2+</sup> release via the RyR1 is finely controlled by number of proteins, small molecules and post-translational modifications that influence opening or closing of the channel (Fig. 10).

(i) **FK506-binding proteins (FKBPs)** 12 and 12.6 interact with all three RyR isoforms, more specifically FKPB12 co-purifies with RyR1 and FKBP12.6 with RyR2. FKBP12 is involved in stabilization of the closed state of the channels and prevents the occurrence of subconductance states [117]. Cryo-EM studies have shown that FKBP12 binds to a site near subdomains 3, 5 and 9 [118, 119].

(ii) **Calmodulin (CaM)** is a 17kDa protein that binds to the cytoplasmic domain of the ryanodine receptor and affects its activity in a different manner depending on whether Ca<sup>2+</sup> is bound or not. When it is in Ca<sup>2+</sup>-free state or ApoCaM, it acts as a partial agonist, activating RyR1 and inhibiting RyR2, while at high Ca<sup>2+</sup> concentrations in the Ca<sup>2+</sup>-bound form known as CaCaM, it acts as an inhibitor of both RyR1 and RyR2 [73, 120]. ApoCaM and CaCaM bind to different RyR1 domains, but some regions contained within residues 3614-3643 and 2937-3225 can act as binding sites for both states of calmodulin [121, 122]. Cryo-EM studies have identified the binding domains of apo-CaM and Ca<sup>2+</sup>/CaM on RyR1 [123]. According to this study the position of CaM on the 3D structure changes after Ca<sup>2+</sup> binding.

(iii) **Calsequestrin** is Ca<sup>2+</sup> buffering protein located in the lumen of the SR. Depending on the intraluminal Ca<sup>2+</sup> levels, it can form oligomers and interact with junctin and triadin. It is believed that the calsequestrin-triadin-junctin complex can affect RyR activity, although the precise mechanism of action to achieve this effect has not been unraveled [124]. See the subsequent section for more information on calsequestrin.

(iv) **Phosphorylation:** Kinases such as PKA and CaMKII, as well as phosphatases such as PP1, PP2A and PDE4D3 target RyRs. Some of these enzymes are docked onto the RyRs through scaffolding proteins [125]. At least two residues in human RyRs are phosphorylated by PKA, namely Ser2843 in RyR1 and Ser2030, Ser2808 in RyR2.

(v) **CaMKII** is regulated by intracellular  $\text{Ca}^{2+}$  concentrations via CaM. It can phosphorylate Ser2843 in RyR1 and Ser2808 in RyR2 but also seems to have a unique phosphorylation site in RyR2 (Ser2814). CaMKII was found to increase the open probability and  $\text{Ca}^{2+}$  sensitivity of the channel and has also been shown to contribute to cardiac arrhythmia and contractile dysfunction [126].

**Figure 10: Binding partners and ligands of RyR.** (A) Schematic overview of the RyR and voltage-gated calcium channel ( $\text{Ca}_v$ ), present in two different membranes, along with several binding partners in the cytoplasmic and luminal areas. 4-CmC, 4-chloro-m-cresol. (B) Locations of several protein-binding partners based on difference cryo-EM [127].

## DHPR skeletal ( $\text{Ca}_v1.1$ ) and cardiac ( $\text{Ca}_v1.2$ ) isoforms

$\text{Ca}_v1.1$  and  $\text{Ca}_v1.2$  are the voltage gated calcium channels and together with the voltage-gated potassium and sodium channels, are members of the gene superfamily of transmembrane ion channel proteins. The  $\alpha_1$  subunit having an approximate molecular mass of 190-250 KDa is the biggest subunit and acts as the voltage sensor and gate. The  $\alpha_1$  subunit is organized in four homologous domains (I-IV) (Fig. 11) with six transmembrane segments in each domain (S1-S6). Channel regulation by second messengers, drugs and toxins occurs through known sites within the alpha 1 subunit. The S4 segment is responsible for voltage sensing, while the pore loop between S5 and S6 in each domain determines ion selectivity and conductance.

**Figure 11: Illustrated model of  $\text{Ca}_v1.1$  subunit composition of channels isolated from skeletal muscle.** Model fits to the current available data for  $\text{Ca}_v2$  channels as well.

The  $\text{Ca}_v1$  subfamily ( $\text{Ca}_v1.1$  to  $\text{Ca}_v1.4$ ) includes channels with  $\alpha_{1S}$ ,  $\alpha_{1C}$ ,  $\alpha_{1D}$  and  $\alpha_{1F}$  which mediate L-type  $\text{Ca}^{2+}$  currents. The genes encoding the different  $\alpha_1$  subunits are not clustered on a single chromosome even for the close members of the family (Fig. 12) [128].

**Figure 12:  $Ca_v\alpha_1$  subunit gene tree.** Full-length amino acid sequences for all 10 human  $Ca_v\alpha_1$  genes were aligned using a branch and bound tree search with maximum parsimony (Genetic Computer Group, paupsearch and paupdisplay programs). Confidence values for each node were determined by bootstrap analysis. All unlabeled nodes represent 100% confidence [129].

It was shown that the cytoplasmic II-II loop of the skeletal DHPR  $\alpha_1$  subunit is necessary for the functional DHPR-RyR1 interaction (Fig. 13). Other regions may play a role in the interaction but this area seems to be essential. The nature of the DHPR-RyR interaction is tissue specific, in skeletal muscle the physical interaction occurs through direct contact of the two proteins, while in cardiac muscle DHPR acts as a mediator of a small influx of  $Ca^{2+}$  which leads to the RyR2 channel activation [39].

**Figure 13: Interaction of RyR1 and RyR3 with skeletal DHPRs.** (A) and (B) In dyspedic 1B5 cells (RyR1  $-/-$ ), DHPRs are clustered in correspondence of CRUs, but they are not grouped in tetrads as in normal skeletal muscle cells because of lack of RyR type 1 in the SR junctional domains. (C) and (D) DHPR tetrad arrangement is restored by transfection with cDNA encoding for RyR1. Dotting the center of tetrads in the array (C, bottom) results in an ordered pattern that is related to the arrays of feet in the SR. (E) and (F) RyR3 expression does not restore DHPR tetrad arrays suggesting that RyR3 in skeletal muscle cells does not interact directly with DHPRs as RyR1 does. Bar, 0.1  $\mu\text{m}$  (3D reconstruction of RyRs courtesy of T. Wagenknecht) [50].

The  $\text{Ca}_v1.2$  gene ( $\alpha_{1C}$ ) is expressed in a variety of cells including ventricular cardiac muscle, smooth muscle, pancreatic cells, fibroblasts, and neurons his channel opens as the membrane potential depolarizes beyond about  $-30$  mV.  $\text{Ca}_v1.2$  channels help define the shape of the action potential in cardiac and smooth muscle. These channels function primarily as calcium ion channels and, unlike  $\text{Ca}_v1.1$  of skeletal muscle, calcium flow through  $\text{Ca}_v1.2$  is an essential step in initiating the signaling cascade that leads to cardiac and smooth muscle contraction [39].

## **Sarcoendoplasmic reticulum Ca<sup>2+</sup>-ATPase SERCA**

SERCAs are members of the P-type ATPases; they are made up of a single polypeptide of 110KDa and can be found in the ER and SR membrane. This group of ATPases is characterized by the transfer of the terminal phosphate from ATP to an aspartate residue in the catalytic domain inducing a reversible conformational change. SERCA uses the energy obtained from ATP hydrolysis to transport Ca<sup>2+</sup> across the ER/SR membrane. For every hydrolyzed ATP molecule, two Ca<sup>2+</sup> ions are transported. The activity of SERCA pumps is regulated by phospholamban and sarcolipin in a tissue specific manner.

There are three genes encoding SERCA 1, 2 and 3. SERCA1 is found in fast-twitch skeletal muscle and has two isoforms SERCA1a adult and SERCA1b fetal. SERCA2a is found mostly in cardiac and slow-twitch skeletal muscles, while SERCA2b is expressed to low extent in all tissues. Recently a new isoform has been reported in cardiac muscle named SERCA2c. SERCA3 isoforms are found in non-muscle tissues mainly in hematopoietic cell lineages, platelets, epithelial cells, fibroblasts and endothelial cells. Low levels of this isoform have been detected in muscle tissue as well. The primary structure of SERCA isoforms is highly conserved. Thapsigargin inhibits all SERCA isoforms, and shows no effect on Na<sup>+</sup>/K<sup>+</sup> or other ATPases [130].

## **Sarcalumenin**

In the longitudinal section of skeletal and cardiac sarcoplasmic reticulum two alternative splice products of the same gene known as 160 kDa sarcalumenin and 53 kDa glycoprotein are present at low levels. Sarcalumenins are high capacity low affinity Ca<sup>2+</sup> binding proteins while the 53 kDa glycoprotein does not bind Ca<sup>2+</sup> as it lacks the NH<sub>2</sub> terminus [131]. Sarcalumenin knockout (SARKO) mice exhibit mild cardiac dysfunction and show reduced SERCA activity and SERCA protein content [132], however sarcalumenin deficiency leads to progressive heart failure in response to pressure overload [133].

## **Triadin**

The single triadin gene *TRDN* gives rise to different isoforms formed by alternative splicing. In rat skeletal muscle three isoforms of triadin have been found, namely Trisk 95, Trisk 51 and Trisk 32. Trisk 95 and Trisk 51 are expressed only in skeletal muscle where they localize to the triads and in association with RyR1 and CSQ1. Trisk 32 is the main cardiac isoform found in skeletal muscle it is expressed at low levels in the whole SR [134]. Triadin KO mice show cardiac and skeletal muscle impairments, with moderate muscle weakness and reduction in the amplitude of the  $\text{Ca}^{2+}$  transient. Isoproterenol induced arrhythmias were observed at the level of cardiac muscle [134].

## **Junctin**

Junctin was first identified as a 26-kDa calsequestrin-binding protein in cardiac and skeletal muscle junctional SR membranes. It was originally proposed that junctin is responsible for anchoring calsequestrin to the SR membrane in proximity to the ryanodine receptor and indeed it was later shown that junctin binds to both calsequestrin and the ryanodine receptor as well as triadin. Results from our laboratory provide strong support for a model in which a quaternary protein complex exists between junctin, triadin, calsequestrin, and the ryanodine receptor at the junctional SR membrane. This complex may be important for operation of  $\text{Ca}^{2+}$  release during excitation-contraction coupling in cardiac and skeletal muscle [135]. The close structural similarities between junctin and triadin suggest that both proteins have related functions.

## **Mitsugumin 29**

According to its name mitsugumin29 is a 29kDa protein found in SR/ER membrane. It is localized in the triad junction of the skeletal muscle. It shares close to 45% homology with synaptophysin, a family of proteins with a role in secretion and release of the neurotransmitters. Mice lacking Mg29 showed reduced contractile force, altered structure of the triadic junction and are prone to fatigue indicating that this protein has a role in ECC [131, 136].

## **Junctophilin-1**

There are at least three junctophilin isoforms encoded by distinct genes: junctophilin-1 is expressed in skeletal muscle, while junctophilin-2 and -3 are expressed in heart and brain. Junctophilin-1 a 72 kDa protein whose function is to physically link the T-tubules with the SR membrane via a probable phospholipid mediated interaction. KO mice for this gene die within 20h after birth [131].

## **JP-45**

This protein is a 45 kDa transmembrane protein found in the skeletal muscle junctional face membrane, with highest expression levels during the second postnatal month. It was originally identified as a protein which is weakly phosphorylated by cAMP-dependent protein kinase and co-elutes with the DHPR from a heparin-agarose column [137]. Co-immunoprecipitation experiments showed that JP-45 is not part of the RyR1 macromolecular complex but rather it interacts with calsequestrin via its luminal carboxy-terminal domain and with  $Ca_v1.1$ , through its cytoplasmic amino terminus. Skeletal muscles of young JP-45 KO mice exhibit characteristics of muscles from aged mice such as decreased levels of  $Ca_v1.1$  content/density in the SR membrane [138].

## **Parvalbumin**

Parvalbumin is a high-affinity calcium-binding protein found in a limited number of vertebrate tissues, including skeletal muscle and specific nerve cells. The highest levels of parvalbumin are found in the fast-contracting and fast-relaxing skeletal muscles, while in slow-twitch skeletal muscles, cardiac and smooth muscles, little or no parvalbumin is expressed. Parvalbumin contains two high-affinity  $Ca^{2+}$ -binding sites that are occupied by  $Mg^{2+}$  under resting conditions. Upon cell activation,  $[Ca^{2+}]_i$  rises to micromolar levels, and  $Mg^{2+}$  ions are replaced by calcium ions. The  $Ca^{2+}$  association rate of parvalbumin is slower than the rate of  $Ca^{2+}$  binding to troponin C. For that reason,  $Ca^{2+}$  binds preferentially to troponin C during muscle activation, and the parvalbumin-buffering activity is delayed. On the basis of these observations, parvalbumin is expected to promote the relaxation of fast-contracting skeletal muscles [139].

## 1.2.4 Ryanodine receptor related neuromuscular disorders

Mutations in both receptors *RYR1* and *RYR2* have been linked to a number of genetic diseases [140, 141]. So far there is no described disease phenotype associated with mutations in *RYR3*.

Most of the mutations in *RYR1* and *RYR2* are found at domain-domain boundaries, either in between the three domains or at interfaces with neighboring RyR domains. This indicates that some domain interactions may be disrupted during channel opening and that mutations facilitate the opening of the channel by weakening these contacts. Most of the mutations are at interfaces with other N-terminal hot spot domains, either within or across subunits. The zipper hypothesis, involving interactions with the central hot spot region, can apply to only less than one-third of the N-terminal mutations [127]

In the section below I will only discuss disorders relating to mutations in *RYR1*, where both dominant and recessive mutations have been identified and are associated with several muscle disorders, including Malignant hyperthermia (MH), central core disease (CCD), multi-minicore disease (MmD), Centronuclear myopathy (CNM), core-rod myopathy and congenital fiber type disproportion (CFTD) [142-144].

### **Malignant Hyperthermia**

Malignant hyperthermia (MH) is a pharmacogenetic disorder induced by volatile anesthetics or depolarizing muscle agents, characterized by muscle rigidity, rhabdomyolysis, tachycardia, metabolic acidosis and a fatal rise in body temperature [80, 145, 146]. It is typically triggered by the combination of a *RYR1* mutation and an external compound such as a volatile anesthetic or the muscle relaxant succinylcholine. In some cases, stress may serve as an alternative external trigger [147]. In general, most MH susceptible individuals have unaffected muscle function as long as they are not exposed to triggering agents. Patients with congenital myopathies with mutations in *RYR1* receptors can be at risk of an MH reaction during general anesthesia.

During an MH event, an excessive leak of  $\text{Ca}^{2+}$  from the SR results in a hypermetabolic state, depleting the ATP pool and leading to acidosis. Dantrolene is a clinically approved drug to treat MH and acts by decreasing the SR  $\text{Ca}^{2+}$  release [148]. According to several studies there is a direct interaction between dantrolene and RyR1 [149]. Dantrolene inhibits RyR1  $\text{Ca}^{2+}$  release from HEK 293 cells transfected with *RYR1* cDNA and appears to inhibit store overload-induced calcium release (SOICR) [150]. On the other hand, the single-channel behavior of RyR1 incorporated in planar lipid bilayers appears to be unaffected by dantrolene.

### Central core disease (CCD)

Central core disease is a dominantly inherited neuromuscular disorder characterized histologically by centrally located areas of reduced oxidative activity and spanning the entire longitudinal axis of the muscle fiber and with clinical features of congenital myopathy (Fig. 14) [151].

**Figure 14: Histopathologic appearance of typical central core disease.** NADH-TR, transverse section from the rectus femoris. Marked predominance of dark staining, high oxidative type 1 fibres with cores affecting the majority of fibres. Cores are typically well demarcated and centrally located ( $\rightarrow$ ), but may occasionally be multiple and of eccentric location [151].

The symptoms include hypotonia appearing in infancy or in early childhood with a delay in motor development. Stiffness and weakness of the muscles are a feature of CCD and distribution of the weakness is usually proximal with the involvement of the hip girdle and axial muscles; in rare cases facial wasting is present as well. As part of the weak facial involvement, inability to bury eyelashes fully appears, while the extraocular muscle involvement was proposed to be an exclusive indicator for the presence of the recessive *RYR1* mutations [151]. Cardiomyopathies in general are not associated with CCD. Scoliosis, congenital dislocation of the hips, foot deformities are also part of the phenotype of this disorder. So far, there has been no association between the number of cores in muscle biopsy and the severity of the muscle weakness. Many patients with CCD are positive for the malignant hyperthermia susceptibility (MHS) in vitro contracture test (IVCT) and should be considered at risk for malignant hyperthermia during general anesthesia [151].

Around 40 different missense mutations and small deletions in the human *RYR1* gene have been associated with CCD [152]. There are three regions of the RyR1 protein where MH and CCD causing mutations were identified. The first domain is from residue 1-614, the second from 2101-2458 and the third from 3916-4973 [153]. According to recent studies patients with CCD predominantly have point mutations and in-frame deletions in the C-terminal region of the *RYR1* [154] [155].

The functional effects of *RYR1* mutations associated with CCD have been primarily investigated by expressing the mutated RYR1 channel in myotubes derived from *RYR1*-KO mice, in primary myotube cultures and lymphoblastoid cell lines derived from patients. According to these studies, there are two mechanisms by which missense mutations affect  $\text{Ca}^{2+}$  release during ECC. The first mechanism is by enhancing  $\text{Ca}^{2+}$  leak from the SR into the cytosol leading to depleted SR stores [156] [157]. The second mechanism is the “uncoupling model” where the mutations affect the capacity of channels to transport  $\text{Ca}^{2+}$  from the SR following depolarization or direct ligand activation [156]. It seems that RYR1 mutations linked to CCD located in the first and second domain are associated with  $\text{Ca}^{2+}$  leak from the SR, while mutations in the third domain are responsible for EC uncoupling, though this might not be exclusive, as some leak-inducing mutations have been identified in the third domain as well [152].

## **Multi-minicore disease (MmD)**

Multi-minicore Disease (MmD) is an inherited neuromuscular disorder which is characterized by the presence of multiple areas with reduced oxidative activity (called minicores) running along a limited area of the longitudinal axis of the muscle fiber. Symptoms of MmD appear in infancy or in early childhood and the most prominent ones are hypotonia with delayed motor development. Other symptoms associated with the presence of minicores include spinal rigidity, scoliosis and respiratory impairment. These are usually indicators of a classical MmD phenotype. Since it appears in life, feeding problems can be present and slow the rate of growth and weight gain. Axial muscle weakness in the neck and trunk area are common and indicative of MmD.

### **Clinical characteristics:**

Multiminicore disease (MmD) is broadly classified into four groups:

- Classic form (75% of individuals)
- Moderate form, with hand involvement (<10%)
- Antenatal form, with arthrogryposis multiplex congenita (<10%)
- Ophthalmoplegic form (<10%)

In general, the diagnosis of MmD is based on the presence of multiple "minicores" visible on muscle biopsy using oxidative stains, identification of static or slowly progressive weakness, and absence of findings diagnostic of other neuromuscular disorders. 50% of MmD patients have causative mutations in *SEPNI* and *RYR1* (Fig. 15).

The severe, classic form of multiminicore disease is usually caused by mutations in the *SEPNI* gene. This gene encodes a protein called selenoprotein N. Although its function is unknown, researchers suspect that it may play a role in the formation of muscle tissue before birth but it must also be important for normal muscle function. It is unclear, however, how mutations in the *SEPNI* gene lead to muscle weakness and other features of multiminicore disease [158]. The so called ophthalmoplegic form encompasses patients with weakness and wasting of muscles similar to the classic phenotype, however such patients also exhibit specific weakness of the extraocular muscles or external ophthalmoplegia that is pronounced on abduction and upward gaze. In this group respiratory impairment is not so pronounced as in the classic form [159].

Predominant hip girdle weakness with relative sparing of respiratory and bulbar muscles similar to the pattern in patients with CCD is observed in another subgroup of MmD; some patients may show additional marked distal weakness and wasting, predominantly affecting the hands in the so called moderate form of MmD with hand involvement. [160]. The pattern of selective involvement on muscle imaging is similar to that observed in classic CCD caused by dominant *RYR1* mutations and distinct from the selective muscle involvement described in myopathies due to recessive mutations in the *SEPN1* gene. The latter two groups may form part of a clinical spectrum rather than distinct entities, as suggested by the observation of extra-ocular muscle involvement evolving over time in patients with the moderate form of MmD. Few severely affected cases have been reported with antenatal onset, generalized arthrogryposis, dysmorphic features and mild to moderate reduction of respiratory function.

**Figure 15: Schematic representation of the skeletal muscle ryanodine receptor (*RYR1*) gene and distribution of dominant and recessive (\*) mutations associated with central core disease (CCD, in black) and Multi-minicore Disease (MmD, in red). Dominant mutations associated with a CCD phenotype predominantly affect the *RYR1* C-terminal domain encoding the calcium release channel pore of the ryanodine receptor protein, whereas recessive mutations predominantly associated with a MmD phenotype are distributed evenly throughout the gene. N-terminal, central and C-terminal mutational hotspots within the *RYR1* gene are highlighted in grey. (Figure courtesy of Dr Haiyan Zhou) [158].**

## Centronuclear myopathy (CNM)

Centronuclear myopathy (CNM) is a genetically heterogeneous condition characterized by the prominence of centrally located nuclei on muscle biopsy and clinical features of a congenital myopathy (Fig. 16). The severe X-linked recessive form is associated with mutations in the myotubularin1 (*MTM1*) gene. Dominant mutations in dynamin 2 gene (*DNM2*) and *RYR1* and recessive in amphiphysin 2 (*BINI*) mutations have been associated with a milder phenotype. Extraocular muscle involvement is common in all forms of CNM. The *MTM1*, *DNM2*, and *BINI* genes all encode proteins with a role in different aspects of membrane trafficking and remodeling [144].

The most severe X-linked form of the disease is caused by mutation in the Xq28 region which encodes *MTM1* or the protein called myotubularin.1. Most mutations cause very low levels of expression if any of myotubularin in the muscle fibres. This protein plays a role in phospholipid signaling as it regulates the levels of PI3phosphate and PI3,5P by dephosphorylating these phospholipids. Affected muscle fibers have a phenotype of a fetal/immature muscle. Boys with the X-linked recessive form, show very early symptoms, with poor muscle tone and severe weakness, including breathing difficulties. Other symptoms include undescended testicles (testes retention), weak eye musculature and a larger head than normal, with or without hydrocephalus. In the most severe form, myotubular myopathy, muscle weakness and respiratory problems are often so severe that the child dies during the first year of life.

The *DNM2* mutation on chromosome 19p13.2 is the cause of the autosomal dominant form of the disease. The dynamin 2 protein is involved in the formation of muscles cell membranes and formation of T tubules. The symptoms of the disease are mild and they appear in late childhood or in adult age. Mutations in *RYR1* cause the dominant form of the disease and symptoms appear in the neonatal period or later. Mutations in *MTMR14* and *MYF6* have been discovered in rare cases causing the dominant form of CNM. The phenotypes of the patients are very similar and slightly milder than those caused by *DNM2* or *RYR1* mutations and can include respiratory difficulties to stiff joints and scoliosis

The recessive form of the disease is caused by mutations in *BINI* which is responsible for the expression of the amphiphysin 2, a protein enabling dynamin 2 regulation of T tubule formation and transport of membrane proteins within muscle cells. In this form of the disease, muscle weakness appears in childhood and initially is most apparent in the upper arms, thighs, face and eye muscles. The latter causes squinting and drooping of the upper eyelids known as ptosis [151]. All three major forms of centronuclear myopathy are rare occurring in less than 10 individuals per 100 000.

**Figure 16: Histopathological features of RYR1-related centronuclear myopathy.**

Haematoxylin and eosin (H&E) (a and c), NADH-tetrazolium reductase (NADH-TR) (b) and cytochrome oxidase (COX) (d), stains from muscle biopsies taken from the left quadriceps at 1 year (a and b) and the right tibialis anterior at 9 years of age (c and d). With H&E stain at 1 year of age (a), there is hypotrophy and hypertrophy of two populations of fibres with numerous central nuclei mainly in smaller fibres. The smaller fibres are darker with NADH-TR and show central accumulation of stain (b). With H&E stain at 9 years of age (c), in addition to central nuclei there is a mild increase in connective tissue and staining for COX shows core-like areas devoid of activity that are often central (d, arrows) . Bars = 50 nm. [161].

## **Congenital fiber type disproportion (CFTD)**

Congenital fiber type disproportion is a rare muscle disease with first symptoms appearing at birth or within the first five years of life. Most apparent symptoms include loss of muscle tone (hypotonia) and generalized muscle weakness (myopathy) particularly in the muscles of the shoulders, upper arms, hips and thighs. Weakness can also affect muscles of the face and muscles controlling eye movement (EOM) and in some cases causing droopy eyelid (ptosis). If the muscle weakness is pronounced scoliosis appears, in addition to dislocated hips and the permanent fixation of joints in a flexed position (contracture). Delays in motor development are present in the majority of cases.

Establishing the correct diagnosis for this disease can be quite demanding, as the changes occurring in the muscle tissue can appear in association with other disorders such as congenital muscle disorders, spinal muscular dystrophy, metabolic conditions, etc. In some cases CFTD is inherited as autosomal recessive or dominant trait [162]. Approximately 30% of patients have mild to severe respiratory involvement and feeding difficulties. It is estimated that up to 25 percent of affected individuals experience severe muscle weakness at birth and die in infancy or childhood. Muscle weakness generally does not worsen over time, and in some cases may improve. The histochemical pattern of muscle biopsies includes predominance of the type 1 fibers, which are around 12% or more smaller than type 2 fibers. Type 2 fibers remain normal or hypertrophic [162].

Mutations in the *TPM3* have been identified as common cause of CFTD. Mutations in the  $\alpha$ -skeletal actin (*ACTA1*) gene have been identified in severe cases of CFTD, but the molecular mechanisms leading to disproportion in fiber size are unknown [163], it is still unknown if the *ACTA1* mutations are involved in the milder cases of CFTD. Causative mutations have been identified in *TPM2* and *SEPN1* as well. The genetic cause is still not known for approximately 50% of the cases.

Recently in a study of Clarke et al. mutations in *RYR1* were identified in 4 families with typical CFTD in whom no other genetic cause was found. From the cohort of patients used in this study it was estimated that 10-20% of CFTD cases are due to mutations in *RYR1* [143]. The pathophysiological effect of the *RYR1* mutations is not known, though reduced channel activity as a consequence of the low expression of RyR1 in the muscle of some patients with recessive form of the disease has been postulated [164]. The presence of

ophthalmoplegia could be a specific clinical indicator for the presence of mutations in *RYR1* in the CFTD patients, since this symptom is not present in patients with other genetic causes. The difficulty however is that in milder cases, ophthalmoplegia might not be apparent and therefore hard to detect [165].

Although there was no family history of MH in any of the reported families with *RYR1* mutations the novel missense mutations may translate into susceptibility to MH in heterozygous mutation carriers. Since mutation of *RYR1* appears to be a common cause of CFTD, it should be recommended that MH precautions are taken for anesthetics in CFTD patients who do not have a genetic diagnosis [143]. To date molecular testing is clinically available for all genes and completes the diagnosis.

## **1.3 Calcium influx and spontaneous calcium events in muscle cells**

### **1.3.1 Excitation-coupled calcium entry (ECCE)**

Calcium influx in muscle cells is operated by two main mechanisms: excitation-coupled  $\text{Ca}^{2+}$  entry (ECCE) and store-operated  $\text{Ca}^{2+}$  entry (SOCE). ECCE is a form of  $\text{Ca}^{2+}$  entry from the extracellular environment into the myoplasm, which requires the interaction between DHPR and RyR1 as it was shown that in dyspedic and dysgenic myotubes ECCE does not occur. ECCE is activated in muscle cells following prolonged membrane depolarization.

ECCE is enhanced in myotubes expressing *RYR1* constructs that carry mutations causing malignant hyperthermia in humans. This increase in ECCE may contribute to the pathophysiological increase in intracellular  $\text{Ca}^{2+}$  that occurs during episodes of malignant hyperthermia. It appears that ECCE may be important in normal skeletal muscle as well, to help maintain force generation during tetanic stimulation. ECCE is blocked by 2-aminoethyl diphenylborate (2-APB), SKF 96356,  $\text{La}^{3+}$ ,  $\text{Gd}^{3+}$  and 50 $\mu\text{M}$  nifedipine. ECCE can occur without any store depletion or in cells in which stores are fully depleted [40].

### 1.3.2 Store-operated calcium entry (SOCE)

SOCE was originally characterized in non-excitabile cells but was studied in skeletal muscles following the discovery of stromal interaction molecule 1 (STIM1) and Orai1. SOCE is a process whereby  $\text{Ca}^{2+}$  influx across the plasma membrane is activated in response to depletion of intracellular  $\text{Ca}^{2+}$  stores in the ER/SR, thus it is an important process involved in maintaining intracellular calcium stores.

STIM1 is a transmembrane phosphoprotein containing several domains which include an EF-hand domain, a sterile- $\alpha$ -motif (SAM) domain at the N-terminus, and two coiled-coil regions and a proline-rich region at the C-terminus. The EF-hand domain of STIM1 has a high affinity for calcium and is located in the lumen of the endoplasmic reticulum (ER), where it is thought to sense changes in calcium store content. The coiled-coil domains are located in the cytosolic C-terminus and are important for oligomerization and punctae formation which occur during the activation of store-operated calcium (SOC) channels. The Orai channel family consists of three family members that form a highly selective calcium channel by tetramerization. STIM1 and Orai1 are both expressed in skeletal muscle, and mice lacking STIM1 and Orai1 display reduced muscle mass.

Three basic models for SOCE have been proposed in recent years: two of these involve conformational coupling between the Transient Receptor Potential channels (TRPC) and either the inositol trisphosphate receptor (IP3R) and/or RYR1 and a third that involves the physical interaction of STIM1 and Orai1 [166].

### 1.3.3 Sparks

The term  $\text{Ca}^{2+}$  spark was used for the first time by Chen and Lederer to describe spontaneous subcellular  $\text{Ca}^{2+}$  release events [167].  $\text{Ca}^{2+}$  sparks are small, brief and very localized releases of  $\text{Ca}^{2+}$  and were originally described in cardiac myocytes and later in amphibian skeletal muscles. They appear spontaneously in frog skeletal muscle fibers at rest and at higher frequency during depolarization [168]. In general, sparks and other local  $\text{Ca}^{2+}$  events are described and quantified by their amplitude expressed in  $[\text{Ca}^{2+}]$  or as normalized

increase of fluorescence,  $\Delta F/F_0$ , by the duration measured as full duration at half maximal amplitude (FDHM) and by their width measured as full width at half maximal amplitude (FWHM). The decay of the sparks occurs through diffusional dissipation of the  $\text{Ca}^{2+}$  signal away from its source [169].

$\text{Ca}^{2+}$  sparks were also discovered in smooth muscle cells two years after their initial report in cardiomyocytes [170]. In unstimulated single cardiac myocytes, a  $\text{Ca}^{2+}$  spark appears suddenly, reaches its peak of about a two-fold increase in fluorescence intensity within 10 ms, and disappears in a matter of 20 ms. It is defined by an area of  $\sim 2.0 \mu\text{m}$  in diameter. Spontaneous  $\text{Ca}^{2+}$  sparks do not require  $\text{Ca}^{2+}$  entry into the myocyte through DHPR or by other channels on the plasma membrane. At a resting membrane potential of -80mV spontaneous sparks appear even when extracellular  $\text{Ca}^{2+}$  is removed for a short period [53].

$\text{Ca}^{2+}$  sparks also occur even after the L-type calcium channels have been blocked pharmacologically. Saponin-permeabilised myocytes also exhibit sparks indicating that the membrane integrity is not a prerequisite for these events. It is now accepted that spontaneous  $\text{Ca}^{2+}$  sparks are due to the small but limited opening of RyRs that depends on many factors including  $[\text{Ca}^{2+}]_i$  and  $[\text{Ca}^{2+}]_{\text{SR}}$ , the free  $\text{Ca}^{2+}$  concentration in the cytosol and in the SR lumen, respectively. At supramicromolar concentrations, ryanodine abolishes sparks altogether.

$\text{Ca}^{2+}$  sparks occur in skeletal and smooth muscles, cardiac myocytes, neuroendocrine cells and neurons containing different isoforms of RyRs. Localized  $\text{Ca}^{2+}$  release events with characteristics similar to sparks have also been observed in some non-excitabile cells, including endothelial cells [167].

In vertebrate skeletal muscles, type 1 RyRs form a “double checkerboard” arrangement where unconnected RyRs are in direct contact with those that are engaged with DHPRs. Under normal conditions in mammalian skeletal muscles sparks do not occur as the highly ordered checkerboard conformation is thought to inhibit sparks as the DHPR blocks RyR1  $\text{Ca}^{2+}$  release. Experimentally under non-physiological conditions and under hypo-osmotic stress,  $\text{Ca}^{2+}$  sparks were induced in isolated mouse skeletal muscle fibers [167].

# CHAPTER 2: RESULTS

## 2.1 Excitation-contraction coupling and $\text{Ca}^{2+}$ homeostasis in human craniofacial muscles

### 2.1.1 Introduction

There are approximately 60 distinct skeletal muscles in the vertebrate head that control food intake, facial expression and eye movement. These muscles develop in a manner that is tightly coordinated with other craniofacial tissues. In recent years, interest in this unique group of skeletal muscles has significantly increased, with the accumulation of new information in terms of molecular profiling and gene targeting studies. From a clinical point of view they are coming into the spotlight, especially when it comes to diseases that affect them (strabismus, laryngeal dystonias, facial paralysis and others), but more intriguing is their selective and non-uniform response in different neuromuscular disorders, where some of them are spared and others heavily affected [4]. For this reason we were interested to resolve some of the questions regarding the similarities and differences between different groups of head muscles in the context of neuromuscular disorders.

Keeping this in mind, we investigated human extraocular muscle samples at different points of maturity, either in mature muscles isolated during corrective eye surgery or in myotubes derived in culture from the muscle biopsies. Our aim was to define the  $\text{Ca}^{2+}$  handling properties of these muscles. Defining the characteristics of EOM as well as those of the distinct but spatially close muscles known as orbicularis oculi was also one of the our aims, Indeed, we found significant differences between human EOM, OO and LM in terms of protein levels of different ECC components as well as in the regulation of  $\text{Ca}^{2+}$  homeostasis.

## 2.1.2 Publication – Characterization of the excitation contraction coupling in human extraocular muscles

Excitation–contraction coupling (ECC) is the physiological mechanism whereby an electrical signal detected by the dihydropyridine receptor, is converted into an increase in  $[Ca^{2+}]$ , via activation of ryanodine receptors (RyRs). Mutations in *RYR1*, the gene encoding RyR1, are the underlying cause of various congenital myopathies including central core disease, multiminicore disease (MmD), some forms of centronuclear myopathy (CNM) and congenital fibre-type disproportion. Interestingly, patients with recessive, but not dominant, *RYR1* mutations show a significant reduction in RyR protein in muscle biopsies as well as ophthalmoplegia. This specific involvement of the extraocular muscles (EOMs) indicates that this group of

muscles may express different amounts of proteins involved in ECC compared with limb muscles. In the present paper, we report that this is indeed the case; in particular the transcripts encoding RyR3, cardiac calsequestrin (CSQ2) and the  $\alpha 1$  subunit of the cardiac dihydropyridine receptor are up-regulated by at least 100-fold, whereas excitation-coupled  $Ca^{2+}$  entry is 3-fold higher. These findings support the hypothesis that EOMs have a unique mode of calcium handling.

Key words: calcium homeostasis, excitation–contraction coupling, gene expression.

## INTRODUCTION

Extraocular muscles (EOMs) are among the fastest and most fatigue-resistant skeletal muscles [1]. More than 20 years ago, they were categorized as a separate group of muscles or ‘allotype’ since they represent a unique group of highly specialized muscles, anatomically and physiologically different from other skeletal muscles [2]. Indeed, their embryonic origin is distinct from that of limb muscles: the former, together with the striated muscles of the face, jaw and throat, develop from the first seven somitomeres whereas the latter derive from somites [3]. In humans, there are six types of EOMs and they are characterized by the presence of two layers: the inner global layer and the outer orbital layer [4]. The fibre type classification of limb muscles does not fit the six fibre types described in EOMs [1] and the innervation of EOMs is also different, as they are innervated by cranial nerves and contain both singly innervated muscle fibres (SIFs) and multiply innervated fibres (MIFs), whereas mammalian limb muscle fibres are singly innervated by motoneurons originating from the spinal cord [5]. The distinct origin and innervation of EOMs are probably responsible for the differences in gene and protein expression that have been described in mammalian EOMs [6].

The ryanodine receptor 1 (RyR1) is the calcium channel of striated skeletal muscle responsible for releasing  $Ca^{2+}$  from the sarcoplasmic reticulum leading to muscle contraction [7,8]. Over the last two decades, more than 200 mutations in *RYR1* (the gene encoding RyR1) have been identified in the human population and linked to neuromuscular disorders and/or the pharmacogenetic disorder malignant hyperthermia [9,10]. Whereas the dominant *RYR1* mutations are predominantly associated with central core disease and/or a susceptibility to malignant hyperthermia,

recessive mutations are found in patients with multiminicore disease (MmD), centronuclear myopathy (CNM) and congenital fibre-type disproportion [10–15]. Interestingly, patients with recessive, but not dominant, *RYR1* mutations show a decreased amount of RyR1 protein in biopsied muscles, as well as specific involvement of EOM (ophthalmoplegia) [11–14,16]. Selective involvement of EOM or lack thereof, also characterizes particular neuromuscular diseases: in myasthenia gravis and mitochondrial myopathies they are the first and most affected muscle group [17] whereas they are characteristically spared from pathology in aging, Duchenne muscular dystrophy and congenital muscular dystrophy [18–20]. Such sparing of EOM in muscular dystrophies has been attributed to constitutive differences between EOM and other skeletal muscles [20] but the factors controlling these differences remain largely unknown.

In order to help clarify the cause(s) for the specific involvement of EOM in patients with recessive *RYR1* mutations, we investigated their excitation–contraction coupling (ECC) machinery and calcium homeostasis. Our results show that there are significant differences between leg muscles (LMs) and EOM; in particular the latter have developed a chimaeric configuration in that they express significantly lower levels of RyR1, the  $\alpha 1$  subunit of the dihydropyridine receptor (Ca<sub>v</sub>1.1) and calsequestrin-1 (CSQ1), whereas the cardiac isoforms of the Ca<sub>v</sub>1.2 and CSQ2 are highly expressed as is RyR3. Such changes result in different characteristics of calcium homeostasis, as myotubes explanted from EOM exhibit a large component of excitation coupled  $Ca^{2+}$  entry (ECCE). The results of the present study shed light on the underlying causes leading to EOM involvement in congenital muscle disorders due to *RYR1* mutations causing a decrease in RyR1 protein.

Abbreviations: Ca<sub>v</sub>,  $\alpha 1$  subunit of the dihydropyridine receptor; CCD, charge-coupled device; CSQ, calsequestrin; ECC, excitation–contraction coupling; ECCE, excitation-coupled  $Ca^{2+}$  entry; EOM, extraocular muscle; LM, leg muscle; NA, numerical aperture; qPCR, quantitative real-time PCR; RyR, ryanodine receptor; SERCA, sarcoplasmic/endoplasmic reticulum  $Ca^{2+}$ -ATPase; TIRF, total internal reflection fluorescence.

## EXPERIMENTAL PROCEDURES

### Human muscle cell cultures

Primary muscle cell cultures were established from fragments of quadriceps muscles obtained from biopsies of healthy donors (five donors) and EOM samples obtained from patients undergoing squint corrective surgery (four donors), as described previously [21,22]. Cells were cultured on laminin-coated 0.17-mm-thick glass coverslips in growth medium (Skeletal Muscle Cell Growth medium; Promo Cell) and induced to differentiate into myotubes by culturing them in differentiation medium (Skeletal Muscle Cell Differentiation medium; Promo Cell) for 7–14 days. This research was carried out in accordance with the Declaration of Helsinki (2013) of the World Medical Association and was approved by the Ethikkommission beider Basel (permit number EK64/12); all subjects gave written informed consent to carry out this work.

### Calcium measurements

Myotubes were loaded with fura-2 (Calbiochem) or fluo-4 (Life Technologies) (final concentration 5  $\mu$ M) in differentiation medium for 30 min at 37°C, after which the coverslips were mounted on to a 37°C thermostatically-controlled chamber which was continuously perfused with Krebs–Ringer medium; individual cells were stimulated by means of a 12- or 8-way 100 mm diameter quartz micro-manifold computer-controlled microperfuser (ALA Scientific Instruments), as described previously [22]. For global changes in the intracellular  $Ca^{2+}$  concentration, the fluorescent ratiometric  $Ca^{2+}$  indicator fura-2 was used. Online measurements were recorded using a fluorescent Axiovert S100 TV inverted microscope (Carl Zeiss) equipped with a 20 $\times$  water-immersion FLUAR objective [0.17 numerical aperture (NA)] and filters (BP 340/380, FT 425, BP 500/530) and attached to a Cascade 128 + CCD (charge-coupled device) camera. Changes in fluorescence were analysed using Metamorph imaging software (Molecular Devices) and the average pixel value for each cell was measured at excitation wavelengths of 340 nm and 380 nm as described previously [21,22]. Fura-2 fluorescent ratio signals were converted into  $[Ca^{2+}]$  using the fura-2  $Ca^{2+}$  imaging calibration kit from Molecular Probes/Invitrogen following the manufacturer's instructions, as previously described [23]. The dynamics of  $[Ca^{2+}]$  influx were investigated by TIRF (total internal reflection fluorescence) microscopy using the fast  $Ca^{2+}$  indicator fluo-4, as described previously [24]. Briefly, differentiated human myotubes were mounted on a thermostatically controlled perfusion chamber, bathed continuously in Krebs–Ringer containing 2 mM  $Ca^{2+}$ . ECCE was measured after the application of 60 mM KCl to myotubes pre-treated with 50  $\mu$ M ryanodine (Calbiochem) to block RyR1-mediated  $Ca^{2+}$  release. Nifedipine (50  $\mu$ M) (Calbiochem) was used to block the dihydropyridine receptor or 0.5 mM EGTA to chelate  $Ca^{2+}$ . Online fluorescence images were acquired using an inverted Nikon TE2000 TIRF microscope equipped with an oil immersion CFI Plan Achromat 60 $\times$  TIRF objective (1.49 NA) and an electron multiplier Hamamatsu CCD camera C9100–13. Data were analysed using Metamorph imaging software (Molecular Devices).

### Quantitative real-time PCR

Total RNA was extracted from muscle biopsies using TRIzol® (Invitrogen) and following the manufacturer's protocol. The RNA was first treated with DNase I (Invitrogen) and then 1000 ng were reverse-transcribed using the high-capacity cDNA reverse

transcription kit (Applied Biosystems); cDNA was amplified by quantitative real-time PCR (qPCR) using SYBR Green technology (Fast SYBR Green Master Mix, Applied Biosystems) as described previously [25]. The sequence of the primers used to amplify and quantify the different genes is given in Supplementary Table S1. qPCR was performed on a 7500 Fast Real-Time PCR machine from Applied Biosystems using the 7500 software v2.3. The standard protocol was selected and the running method consisted of a holding stage at 50°C for 20 s and a denaturing step at 95°C for 10 min, followed by 40 cycles of denaturing at 95°C for 15 s and an extension step at 60°C for 1 min. Gene expression was normalized to expression *ACTN2*, which is present in all muscle fibre types. Results are expressed as fold change compared with expression of the gene in LMs.

### Immunofluorescence

Glass coverslip grown and differentiated myotubes were fixed with 4% paraformaldehyde (made in Phosphate buffered saline (PBS)), permeabilized with 1% Triton in PBS for 20 min and processed as previously described [24]. The following antibodies were used: mouse anti-RyR1 (Thermo Scientific; MA3–925), goat anti- $Ca_v1.1$  (Santa Cruz Biotechnology, sc-8160), rabbit anti- $Ca_v1.2$  (Santa Cruz Biotechnology, sc-25686), Alexa Fluor® 488-conjugated chicken anti-rabbit, Alexa Fluor®-conjugated donkey anti-goat IgG (Life Technologies) and Alexa Fluor®-conjugated goat anti-mouse IgG (Life Technologies). Cells were stained with DAPI (Life Technologies) to visualize nuclei and observed using a Nikon A1R confocal microscope with a CFI Apo TIRF 100 $\times$  (1.49 NA) objective.

### Electrophoresis and immunoblotting

The total sarcoplasmic reticulum fraction was isolated from flash-frozen muscle samples (human EOM, quadriceps muscles and mouse heart) stored in liquid nitrogen as previously described [26]. Protein concentration was determined using Protein Assay Kit II (Bio-Rad Laboratories) using BSA as a standard. SDS/PAGE, protein transfer on to nitrocellulose membranes and immunostaining were performed as described previously [26]. The following primary antibodies were used: mouse anti-RyR1 (Thermo Scientific, MA3–925), goat anti- $Ca_v1.1$  (Santa Cruz Biotechnology, sc-8160), rabbit anti- $Ca_v1.2$  (Santa Cruz Biotechnology, sc-25686), rabbit anti-CSQ-1 (Sigma, C-0743) and CSQ2 (Abcam, ab-3516), goat anti-SERCA1 (sarcoplasmic/endoplasmic reticulum  $Ca^{2+}$ -ATPase 1) (Santa Cruz Biotechnology, sc-8093), goat anti-SERCA2 (Santa Cruz Biotechnology, sc-8095), mouse anti-sarcoplasmic reticulum (Thermo Scientific, MA3-932), goat anti-junctophilin1 (Santa Cruz Biotechnology, sc-51308). Secondary horseradish peroxidase conjugates were Protein G-horseradish peroxidase (Sigma, P8170) and horseradish peroxidase-conjugated goat anti-mouse IgG (Sigma, A2304). The immunopositive bands were visualized by chemiluminescence using the Super Signal West Dura kit (Thermo Scientific) or the chemiluminescence kit from Roche.

### Statistical analysis

Statistical analysis was performed using Student's *t* test for two populations. Values were considered significant when  $P < 0.05$ . When more than two groups were compared, analysis was performed by the ANOVA test followed by the Bonferroni post-hoc test, using the GraphPad Prism 4.0 software. The Origin Pro

**Figure 1** Expression of ECC transcripts and proteins in human EOM biopsies

(A) Gene expression was carried out by qPCR as described in the 'Experimental Procedures' section. Each reaction was carried out in triplicate, in pooled muscle samples from 4–5 biopsies from different individuals. Expression levels were normalized to *ACTN2* expression. Results are expressed as mean fold change (AU, arbitrary units) of transcripts in EOM compared with LMs, the latter were set as 1. Results were analysed using Student's *t* test ( $***P < 0.0001$ ). (B) Western blot analysis of total sarcoplasmic reticulum proteins in human EOM and LMs. Twenty micrograms of protein were loaded per lane and separated on SDS/6% PAGE or SDS/10% PAGE. Blots were probed with the indicated antibodies. Histograms represent the mean  $\pm$  S.E.M. band intensity normalized to SERCA2 content ( $*P < 0.05$ ;  $**P < 0.005$ ;  $***P < 0.0001$ ).

8.6 software was used for generating dose–response curves and calculating  $EC_{50}$  values.

## RESULTS

### Excitation–contraction coupling gene and protein expression levels in human EOM

Figure 1(A) shows the expression level as assessed by qPCR, of the main genes involved in skeletal muscle ECC in EOM biopsies, compared with quadriceps biopsies from healthy donors; the latter were taken as the reference tissue and the expression of the different set of muscle-specific genes in human quadriceps was set as 1. The results represent the mean expression levels of samples pooled from four to five biopsies and are expressed on a logarithmic scale. The most interesting finding is that the expression levels of major genes involved in skeletal muscle ECC, namely *RYR1*, *CACNA1S*, *SERCA1* and *CASQ1* were  $\sim 10$ -fold lower ( $P < 0.0001$ ) than in LM biopsies. Intriguingly, the transcript level of *RYR3* was  $\sim 800$ -fold higher in EOM ( $P < 0.0001$ ). A second interesting result was that the expression

level of *CASQ2* was found to be  $\sim 100$ -fold higher in EOM ( $P < 0.0001$ ) as was that of the structural proteins *TRDN* and *ASPH1* ( $\sim 10$ -fold and  $\sim 1000$ -fold respectively;  $P < 0.0001$ ) and of the calcium buffering and binding proteins *SRL* and *PVALB* (10-fold;  $P < 0.0001$ ). As expected, the *MYH1* transcript level was significantly lower in EOM (100-fold;  $P < 0.0001$ ) than in LMs, since this isoform is mainly expressed in slow-twitch muscles. In contrast, the transcript of *MYH13*, which is the isoform characteristically expressed in eye muscles, was  $\sim 5000$ -fold higher in EOM ( $P < 0.0001$ ), corroborating the validity of our assay. Taken together, these results indicate that the gene expression pattern of the main components involved in ECC of human EOM is specific and distinct from that of other striated skeletal muscles.

In order to confirm the changes in gene expression on the protein level, we prepared the total sarcoplasmic reticulum fractions and probed them with a panel of antibodies against skeletal and cardiac ECC protein components. The protein expression levels were then normalized for SERCA2 whose content was similar in LM and EOM as assessed by real time PCR (Figure 1A) and immunoblotting. Figure 1(B) shows the representative Western

**Figure 2 Cellular localization of RyR1, Ca<sub>v</sub>1.1 and Ca<sub>v</sub>1.2 in differentiated EOM-derived myotubes**

Human myotubes were stained as described in the 'Experimental Procedures' section and visualized with a Nikon A1R confocal microscope equipped with a CFI Apo TIRF 100× objective (1.49 NA). (A) anti-RyR1 (red), (B) anti-Ca<sub>v</sub>1.1 (green), (C) merged image of anti-RyR1, anti-Ca<sub>v</sub>1.1 and DAPI (blue); orange pixels show co-localization between RyR1 and Ca<sub>v</sub>1.1. (D) anti-RyR1 (red), (E) anti-Ca<sub>v</sub>1.2 (green), (F) merged image of anti-RyR1, anti-Ca<sub>v</sub>1.2 and DAPI (blue). Scale bar, 20 μm.

blots and quantitative histograms, as can be seen, for RyR1, Ca<sub>v</sub>1.1, SERCA1 and CSQ1 the protein levels are decreased by more than 50% in EOM compared with LM samples. The cardiac isoform of the RyR2 was not detectable in EOM (Supplementary Figure S1) whereas Ca<sub>v</sub>1.2, the cardiac isoform of the Ca<sub>v</sub>, CSQ2, as well as sarcalumenin, were significantly up-regulated in EOM (2-fold for Ca<sub>v</sub>1.2 and by 50% for CSQ2 and sarcalumenin); qPCR could not be used reliably to compare the expression levels of the Ca<sub>v</sub>1.2 transcript because of its extremely low level of expression in leg skeletal muscles (the reference tissue in the qPCR); its level of expression is comparable with that found in mouse heart microsomes (Supplementary Figure S1).

### Ca<sup>2+</sup> homeostasis in EOM cultured myotubes

Muscle biopsies have been used as a starting material to obtain primary muscle cultures from patients with different neuromuscular disorders and the myotubes that have been obtained have been a useful model to study ECC under normal and pathological conditions [21,22,24,25]. In the present study, we successfully used a protocol similar to that used for LM biopsies, in order to obtain EOM-derived myotubes (Figure 3A). Once a sufficient number of myoblasts grew out of the biopsy, they were further expanded and then induced to differentiate into myotubes. Figure 2 shows photomicrographs of myotubes stained with anti-RyR1 (red, Figure 2A), anti-Ca<sub>v</sub>1.1 (green, Figure 2B) merged plus DAPI (Figure 2C) and anti-RyR1 (red, Figure 2D), anti-Ca<sub>v</sub>1.2 (green, Figure 2E) and merged plus DAPI (Figure 2F) and observed by confocal microscopy. As can be seen, the myotubes are positive for RyR1 and Ca<sub>v</sub>1.1 and the two proteins co-localize within an intracellular membrane compartment, but as previously established [25] their distribution is punctuated, not highly regular and lacks the distinct structure observed in mature fibres. The localization of Ca<sub>v</sub>1.2, however, is clearly different

from that of Ca<sub>v</sub>1.1 (compare Figures 2B and 2E); indeed the Ca<sub>v</sub>1.2 appears to be almost exclusively localized on the plasma membrane. These results point to a potential alternative form of ECC in EOM-derived myotubes and we next studied calcium homeostasis in these cells. Results from LM-derived myotubes from five donors and EOM-derived myotubes from four donors were pooled and averaged. Figure 3(B) shows that the KCl-induced Ca<sup>2+</sup> release from intracellular stores (in the presence of 100 μM La<sup>3+</sup> and therefore reflecting skeletal ECC) was similar in LM and EOM-derived myotubes. However, in EOM-derived myotubes the EC<sub>50</sub> for 4-chloro-*m*-cresol-induced Ca<sup>2+</sup> release was increased (332 ± 26 and 234 ± 58 μM for EOM and LM respectively). Additionally, Figure 3(C) shows that the resting [Ca<sup>2+</sup>] in EOM-derived myotubes is significantly lower than that of LM-derived myotubes ( $P < 0.0001$ ; Student's *t* test), whereas the size of the rapidly releasable intracellular Ca<sup>2+</sup> stores is more than 2-fold larger in EOM-derived myotubes compared with LM-derived myotubes (Figure 3D).

Plasma membrane depolarization of skeletal muscle cells is accompanied by Ca<sup>2+</sup> influx through the dihydropyridine receptor and this phenomenon is defined as ECCE [24,27,28]. We next studied ECCE in EOM-derived myotubes using a TIRF microscope [24]. The top panels in Figure 4(A) show a representative myotube pre-treated with 50 μM ryanodine and stimulated with 60 mM KCl; Figure 4(B) shows a representative Ca<sup>2+</sup> influx trace initiated by the application of 60 mM KCl in EOM-derived myotubes (continuous line) and LM-derived myotubes (dotted line). The change in fluo-4 fluorescence represents Ca<sup>2+</sup> influx via the dihydropyridine receptor and not release from stores as: (i) myotubes were incubated with 50 μM ryanodine in order to block Ca<sup>2+</sup> release via RyR; (ii) pre-incubation of myotubes with ryanodine plus 50 μM nifedipine blocked the Ca<sup>2+</sup> increase (Figure 4C); and (iii) Ca<sup>2+</sup> influx was inhibited when the experiment was performed in Krebs-Ringer solution containing 0.5 mM EGTA (Figure 4C). Thus, compared

**Figure 3** Global calcium homeostasis of EOM-derived myotubes

Myotubes were loaded with 5  $\mu\text{M}$  fura-2 and perfused with Krebs–Ringer medium containing 2 mM  $\text{CaCl}_2$ . For KCl-induced  $\text{Ca}^{2+}$  release, individual cells were perfused with Krebs–Ringer plus 100  $\mu\text{M}$   $\text{La}^{3+}$  and the indicated concentration of KCl was applied using a microperfusion system. (A) Brightfield photomicrograph of a fully-differentiated myotube 5 days after differentiation. (B) KCl dose–response curve of EOM-derived myotubes (filled circles, continuous line) and LM-derived myotubes (empty circles, dotted line). Curves show the changes in peak calcium, expressed as  $[\text{Ca}^{2+}]$  in nM. Each point represents the mean  $\pm$  S.E.M. of a minimum of four to ten different cells. (C) Mean  $\pm$  S.E.M. resting  $[\text{Ca}^{2+}]$  in EOM and LM-derived myotubes. (D) Total amount of  $\text{Ca}^{2+}$  in the sarcoplasmic reticulum. The total amount of rapidly releasable  $\text{Ca}^{2+}$  in the stores was determined by calculating the area under the curve of the transient induced by the application of 1  $\mu\text{M}$  ionomycin plus 500 nM thapsigargin in Krebs–Ringer containing 0.5 mM EGTA. Values represent the mean  $\pm$  S.E.M. of the indicated number of cells. \*\*\* $P < 0.0001$ . Experiments were performed on LM-derived myotubes from five donors and EOM-derived myotubes from four donors. The values represent mean intracellular calcium measurements from coverslips measured on different days.

with LM-derived myotubes, depolarization-induced  $\text{Ca}^{2+}$  influx in EOM myotubes was 3-fold higher (Figure 4D).

## DISCUSSION

In the present study, we characterized the ECC machinery of human EOM and report that these muscles are particular in as much as they express important components of the cardiac ECC machinery; in addition, we report for the first time that primary muscle cell cultures can be obtained from biopsies of patients undergoing squint or corrective surgery. Such myotubes maintain their phenotypic characteristics since they exhibit intracellular calcium regulation that is enhanced compared with primary cultures of LM-derived myotubes. The present study is important as it shows the feasibility of performing such experiments not only in biopsies obtained from normal individuals, but also can be extended to patients suffering from neuromuscular disorders causing ophthalmoplegia.

In a previous study, Porter et al. [29] used a bioinformatic gene profiling approach to identify key differences between murine EOM, LM and jaw muscles. In their study, they scanned the expression pattern for transcripts encoding proteins involved in transcriptional regulation, signal transduction, intermediary metabolism and sarcomeric ECC. As far as the ECC coupling

machinery is concerned, our results do not support their findings as we found significant changes between leg and EOM expression of CSQ1 and CSQ2, RyR1, SERCA1 and  $\text{Ca}_v1.1$ , triadin, sarcoplumenin and parvalbumin and no change in mitsugumin-29. Such inconsistencies may be due to the fact that (i) they used mouse skeletal muscle and we used human biopsies, (ii) we used qPCR on pooled samples; (iii) the biopsies we analysed were derived from patients with strabismus and therefore not ‘normal’ muscles. Indeed the pattern of expression of transcripts in strabismic and normal EOMs has been reported to be different [30]; and (iv) we normalized all qPCR results for the content of the muscle-specific gene *ACTN2*. In support of our findings, it was shown that there are important differences between human EOM and those of other species [31].

An interesting observation of the present report is that EOM express low levels of RyR1 but high levels of RyR3, a finding that may explain why patients with recessive ryanodinopathies leading to decreased expression of RyR1 characteristically show extraocular involvement [11,15] whereas those with dominant *RYR1* mutations do not. It is plausible that since the levels of expression of RyR1 are low in EOM, mutations leading to a further decrease in its level of expression will severely affect muscle function, leading to ophthalmoplegia. In this context, it should be mentioned that the higher levels of RyR3 expressed in EOM do not compensate for the decrease in RyR1, indicating that the RyR3

**Figure 4** EOM-derived myotubes exhibit a larger depolarization-induced  $\text{Ca}^{2+}$  influx compared with LM-derived myotubes

$\text{Ca}^{2+}$  influx induced by addition of 60 mM KCl was monitored using a TIRF microscope in myotubes pre-incubated with 50  $\mu\text{M}$  ryanodine to block RyR1-mediated  $\text{Ca}^{2+}$  release and loaded with 5  $\mu\text{M}$  fluo-4. **(A)** Top panels, pseudocoloured ratiometric images (peak fluorescence after addition of KCl/resting fluorescence) of fluo-4 fluorescence changes after application of KCl to EOM-derived myotubes. **(B)** Representative ECCE trace showing changes in fluo-4 fluorescence in a EOM-derived myotube (continuous line) and LM-derived myotube (dotted line). **(C)** Histogram depicting mean  $\pm$  S.E.M. peak increase of fluo-4 fluorescence induced in EOM-derived myotubes by 60 mM KCl alone (white bar), in cells pre-incubated with 50  $\mu\text{M}$  nifedipine (grey bar) or in cells stimulated with Krebs–Ringer containing 0.5 mM EGTA (black bar). Statistical analysis performed by the ANOVA test followed by the Bonferroni post-hoc test; \* $P < 0.02$ , \*\* $P < 0.005$ . **(D)** Mean  $\pm$  S.E.M. peak increase of fluo-4 fluorescence induced by 60 mM KCl in human EOM-derived myotubes (white bar) compared with LM-derived myotubes (black bar). Experiments were performed on cells grown from three different biopsies on three different days and results were pooled and averaged. Statistical analysis was performed using Student's  $t$  test; \*\*\* $P < 0.0001$ .

isoform must be involved in other aspects of calcium release, cannot be directly activated by the  $\text{Ca}_v1.1$  voltage sensor and cannot functionally replace RyR1. On the other hand, EOM also express high levels of the  $\text{Ca}_v1.2$  and of CSQ [32]; as far as CSQ2 is concerned, it has half the calcium-binding capacity of CSQ1 [33], it is phosphorylated to a higher stoichiometry and at least 50-fold more rapidly [34]. Though the role of phosphorylation is unclear, it is thought to increase the  $\text{Ca}^{2+}$ -binding affinity and to assure that the levels of  $\text{Ca}^{2+}$  near the  $\text{Ca}^{2+}$  release sites are elevated [35]. The observed up-regulation of  $\text{Ca}_v1.2$  is both novel and intriguing as this isoform is mainly expressed in the heart, where it functions as a voltage sensor and  $\text{Ca}^{2+}$  channel, activating RyR2 via a  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release mechanism [36]. In EOM-derived myotubes, this isoform was clearly distributed on the plasma membrane and since RyR2 was not detectable in EOM, either these muscles have evolved a chimaeric cardiac/skeletal ECC, with  $\text{Ca}_v1.2$  activating RyR1, or  $\text{Ca}_v1.2$  may be coupled to RyR3 or it may be involved in  $\text{Ca}^{2+}$  influx following

plasma membrane depolarization. Such chimaeric expressions of RyR isoforms are not uncommon in smooth muscle cells that are reported to express different combinations of calcium channels and L-type voltage sensors, depending on their tissue of origin and physiological requirements [37].

Zeiger et al. [38] showed that rat eye muscle-derived myotubes exhibit superior calcium homeostasis compared with leg tibialis anterior-derived myotubes and release double the amount of calcium after treatment with ionomycin than LM-derived myotubes. The results of the present study support and extend these findings; indeed human EOMs not only have larger intracellular  $\text{Ca}^{2+}$  stores and express different calcium-buffering proteins, but also show lower resting  $[\text{Ca}^{2+}]$  and enhanced depolarization-induced calcium influx (or ECCE). The enhanced calcium-handling capacity may be due to the higher expression levels of CSQ2 and of the calcium-binding proteins parvalbumin and sarcoplumennin. Parvalbumin is a cytosolic high-affinity  $\text{Ca}^{2+}$ -binding protein preferentially expressed in fast

twitch muscles whose function is to promote muscle relaxation [39,40], whereas sarcalumenin is localized on the longitudinal sarcoplasmic reticulum where it is involved in stabilizing the  $\text{Ca}^{2+}$  pump and in maintaining rapid contraction and relaxation rates [41]. The physiological function of depolarization-induced calcium influx is far from clear but it is postulated to be important for refilling of intracellular  $\text{Ca}^{2+}$  stores, which is essential during repetitive stimulation [42,43]. Interestingly EOM-derived myotubes have significantly larger intracellular calcium stores and enhanced  $\text{Ca}^{2+}$  influx and the latter is probably due to the high levels of expression of  $\text{Ca}_v1.2$ .

A final observation resulting from the present study and from a previous study [25] concerns the phenotype of satellite cells; depending on their muscle of origin, be it fast or slow twitch or EOM, the satellite subpopulations are intrinsically different [44] and they maintain the specific characteristics particular to the muscle from which they originated even after explantation and culture.

In conclusion, the present study provides insights into the ECC characteristics of human EOM. Reduced expression of RyR1, CSQ1 and SERCA1 is a feature of great significance in the context of ophthalmoplegia and neuromuscular disorders. Taking into account the importance of exquisitely efficient calcium management in order to achieve the demanding physiological properties of the EOMs, the increased levels of CSQ2, parvalbumin and sarcalumenin together with reported higher depolarization-induced calcium influx and particular high expression of  $\text{Ca}_v1.2$  indicate that this group of muscles which is in constant use, relies on a chimaeric skeletal/cardiac ECC configuration.

## AUTHOR CONTRIBUTION

Marijana Sekulic-Jablanovic performed the experiments, analysed the data and drafted the article. Anja Palmowski-Wolfe performed surgeries, provided the biopsies and critically revised the paper for important intellectual content. Francesco Zorzato was responsible for conception and design of the experiments, interpretation of data and critically revised the paper for important intellectual content. Susan Treves was responsible for conception and design of the experiments, collection, analysis and interpretation of data and drafted the article.

## ACKNOWLEDGEMENTS

We gratefully acknowledge the technical support of Anne-Sylvie Monnet.

## FUNDING

This work was supported by the Swiss National Science Foundation (SNF) [grant number 31003A-146198]; and the Department of Anesthesia Basel University Hospital.

## ABSTRACT

The *orbicularis oculi* are the sphincter muscles of the eyelids and are involved in modulating facial expression. They differ from both limb and extraocular muscles in their histology and biochemistry. Normal *orbicularis oculi* possess some features which, when present in limb or trunk muscles, would be considered consistent with a chronic myopathy or dystrophy. Weakness of the *orbicularis oculi* muscles is present in neuromuscular disorders affecting the neuromuscular junction and weakness of facial muscles and ptosis have also been described in patients with mutations in *RYR1*. In the present paper, we investigated human *orbicularis oculi* muscles and found that they are functionally more similar to quadriceps than to extraocular muscles in terms of skeletal muscle excitation-contraction coupling components. In fact, they do not express the cardiac isoform of the dihydropyridine receptor, which was found to be highly expressed in extraocular muscles and is most likely responsible for the large depolarization induced calcium influx in the latter muscles. On the other hand, human *orbicularis oculi* and extraocular muscles express high levels of utrophin and very low levels of dystrophin, while quadriceps express dystrophin and low levels of utrophin. The results of the present study highlight the notion that myotubes obtained by explanting satellite cells from different muscles are not functionally identical and retain the physiological characteristics of their muscle of origin. Furthermore our results indicate that sparing of facial and extraocular muscles in patients with Duchenne is the result of the higher levels of utrophin expression.

## INTRODUCTION

Excitation-contraction coupling (ECC) is the process whereby an electrical signal, depolarization of the plasma membrane, is converted into a chemical signal,  $\text{Ca}^{2+}$  release from the sarcoplasmic reticulum, leading to muscle contraction (Caputo 2010). ECC relies on the function of two main  $\text{Ca}^{2+}$  channels, the voltage sensing dihydropyridine receptor (DHPR) an L-type  $\text{Ca}^{2+}$  channel present on the transverse tubules and the ryanodine receptor  $\text{Ca}^{2+}$  channel (RyR) present on the sarcoplasmic reticulum terminal cisternae. In mammalian skeletal muscle ECC is mechanically coupled, that is membrane depolarization causes the  $\alpha 1$  subunit ( $\text{Ca}_v1.1$ ) of the DHPR to undergo a conformational change causing it to come in direct contact with the RyR1 and leading to release of  $\text{Ca}^{2+}$  from the sarcoplasmic reticulum (Rios and Pizarro 1991). In mammalian cardiac muscles on the other hand, ECC does not rely on mechanical coupling, but rather influx of  $\text{Ca}^{2+}$  through the cardiac  $\alpha 1$  subunit of the DHPR ( $\text{Ca}_v1.2$ ) activates the cardiac RyR2 leading to release of  $\text{Ca}^{2+}$  from the sarcoplasmic reticulum (Bers 2002). Thus the functional requirements of heart and skeletal muscle are assured by the exquisite specificity of protein isoform expression. This general configuration of skeletal and cardiac ECC protein expression was thought to underlie the function of most striated muscles; however, in a recent study on the protein composition of human extraocular muscles (EOM), we found that hybrid skeletal/cardiac muscle configurations of the ECC machinery can exist. Indeed EOM express both the skeletal and cardiac isoforms of  $\alpha 1$  subunit of the DHPR, rely on influx of  $\text{Ca}^{2+}$  from the extracellular environment and express not only RyR1 but also RyR3 (Sekulic-Jablanovic, Palmowski-Wolfe et al. 2015).

Extraocular muscles (EOM), the fastest muscles in the body, derive from somitomeres (preotic mesodermal segments) (Wright, Hengst et al. 2007). There are six extraocular muscles distributed in three antagonistic pairs of muscles that finely control eye movements (Spencer and Porter 1988); they are innervated by three cranial nerves (III, IV and VI) (Sadeh and Stern 1984). EOM are highly specialized and can be either singly innervated or multiply innervated. These characteristics together with the unique expression of Myosin Heavy Chain-EO (MyHC13) (Schiaffino and Reggiani 2011), sets them apart from all other skeletal muscles, as a distinctive group of highly specialized muscles (Spencer and Porter 1988). The *orbicularis oculi* muscles on the other hand, comprise the sphincter muscles of the eyelids; they are classified as facial muscles and functionally antagonize the *levator palpebrae superior* muscles which are accessory extraocular muscles (Porter, Rafael et al. 1998). The *orbicularis oculi* muscles can be subdivided into orbital, palpebral and lacrimal portions. The orbital portion firmly closes the eyelids and is controlled by voluntary

action; the palpebral portion closes the eyelids gently in involuntary or reflex blinking; the palpebral portion can be further divided into pretarsal, preseptal portion, and ciliary. The lacrimal portion compresses the lacrimal sac, which receives tears from the lacrimal ducts and conveys them into the nasolacrimal duct (Gray and Lewis 1918). The *orbicularis oculi* muscles derive from the mesenchyme in the second pharyngeal arch (Moore, Persaud et al. 2015) and are innervated by the VII cranial nerve (Ouattara, Vacher et al. 2004).

Weakness of the *orbicularis oculi* muscles is often apparent in neuromuscular disorders affecting the neuromuscular junction (Walsh, Newman et al. 2008). Similar to extraocular muscles, they are also one of the first targets of mitochondrial myopathies and Myasthenia gravis, resulting in weakness of eyelid closure usually and ptosis (Walsh, Newman et al. 2008). Facial weakness and ptosis have also been described in patients with recessive *RYR1* mutations (the gene encoding the RyR1) (Taylor, Lachlan et al. 2012), affected by Multi Minicore Disease, Congenital Fiber Type Disproportion and Centronuclear Disease (Jungbluth, Zhou et al. 2005, Treves, Jungbluth et al. 2008, Clarke, Waddell et al. 2010, Wilmschurst, Lillis et al. 2010). On the other hand, EOM are spared in aging, Duchenne muscular dystrophy and Congenital muscular dystrophy when all other skeletal muscles are affected (Kaminski, al-Hakim et al. 1992, Khurana, Prendergast et al. 1995, Kallestad, Hebert et al. 2011). Weakness of the facial musculature caused by any disease is almost certainly accompanied by weakness of the *orbicularis oculi* muscles as well (Walsh, Newman et al. 2008). The present investigation was undertaken in order to identify similarities and differences in ECC and calcium homeostasis in human extraocular muscles, *orbicularis oculi* and quadriceps, in order to identify factors that might contribute to the selective involvement in different neuromuscular disorders. The results of the present investigation show that that the ECC machinery and calcium regulation of human *orbicularis oculi* are more similar to those of quadriceps than of EOM; on the other hand *orbicularis oculi* and EOM are similar in that they both express high levels of utrophin, while quadriceps express dystrophin. This findings explains the sparing of facial and EOM muscles in Duchenne patients; since the ECC machinery between *orbicularis oculi* and quadriceps appears to be similar, our study points to a potential use of autologous facial muscle-derived satellite cells for muscle re-implantation in patients with muscular dystrophy.

## **MATERIALS AND METHODS**

### **Human muscle cell cultures**

Primary muscle cell cultures were established from fragments of quadriceps muscles obtained from biopsies of healthy donors (6 donors), orbicularis oculi muscle samples from patients undergoing eyelid cosmetic procedure or blepharoplasty (5 donors) and extraocular muscle samples obtained from patients undergoing squint corrective surgery (4 donors), as described previously (Censier, Urwyler et al. 1998, Ducreux, Zorzato et al. 2004). Laminin-coated 0.17 mm thick glass coverslips were used for calcium imaging; briefly cells were plated on the coated glass coverslips and allowed to grow in growth medium (Skeletal Muscle Cell Growth Medium, Promo Cell Cat N° C-23080) until cells were approximately 80% confluent at which point they were induced to differentiate into myotubes by switching the medium to differentiation medium (Skeletal Muscle Cell Differentiation medium, Promo Cell, Cat N° C-23061) for 7–14 days. This research was carried out in accordance with the Declaration of Helsinki (2013) of the World Medical Association, and was approved by the Ethikkommission beider Basel (permit N° EK64/12); all subjects gave written informed consent to carry out this work.

### **Calcium measurements**

Fura-2 (Calbiochem) or fluo-4 (Life Technologies, Ltd) at final concentrations of 5  $\mu\text{M}$  were used to load myotubes for 30 min at 37°C, after which the coverslips were mounted onto a 37° C thermostatically controlled chamber that was continuously perfused with Krebs–Ringer medium; individual cells were stimulated by means of a 12- or 8-way 100 mm diameter quartz micromanifold computer-controlled microperfuser (ALA Scientific Instruments, Westbury, NY, USA), as described previously (Ducreux, Zorzato et al. 2004).

The fluorescent ratiometric  $\text{Ca}^{2+}$  indicator fura-2 was used for monitoring the global changes in the intracellular  $\text{Ca}^{2+}$  concentration. Online measurements were recorded using a fluorescent Axiovert S100 TV inverted microscope (Carl Zeiss GmbH, Jena, Germany) equipped with a 20 $\times$  water-immersion FLUAR objective (0.17 N.A.) and filters (BP 340/380, FT 425, BP 500/530) attached to a Cascade 128+ CCD camera Average pixel value for each cell was measured at excitation wavelengths of 340 nm and 380 nm as previously described (Censier, Urwyler et al. 1998, Ducreux, Zorzato et al. 2004). Fura-2 fluorescent ratio signals were converted into  $[\text{Ca}^{2+}]$  using the curve generated using the fura-2  $\text{Ca}^{2+}$  imaging calibration kit from Molecular Probes (Invitrogen) following the manufacturer's instructions and as previously described (Vukcevic, Zorzato et al. 2013). The

dynamics of  $[Ca^{2+}]$  influx were investigated by TIRF microscopy using the fast  $Ca^{2+}$  indicator Fluo-4 as previously described (Treves, Vukcevic et al. 2011). Myotubes were pre-treated with 50  $\mu$ M ryanodine (Calbiochem) in order to block  $Ca^{2+}$  release through the RyR1 receptor and excitation coupled  $Ca^{2+}$  entry (ECCE) was stimulated by the application of 60 mM KCl. Online fluorescence images were acquired using an inverted Nikon TE2000 TIRF microscope equipped with an oil immersion CFI Plan Apochromat 60 $\times$  TIRF objective (1.49 N.A.) and an electron multiplier Hamamatsu CCD camera C9100–13. Metamorph imaging software from Molecular Devices was used for analysis of the fluorescence changes.

### **Quantitative Real-time PCR**

Total RNA was extracted from muscle biopsies using Trizol (Invitrogen) and following the manufacturer's instructions. RNA was first treated with deoxyribonuclease I (Invitrogen) and then 1000 ng were reverse transcribed using the high-capacity cDNA reverse transcription kit (Applied Biosystems). cDNA was amplified by quantitative real-time PCR using SYBR Green technology (Fast SYBR Green Master Mix, Applied Biosystems) as previously described (Rokach, Ullrich et al. 2013). The sequences of the primers used for gene amplification and quantification is given in Supplementary Table 1. qPCR was performed on a 7500 Fast Real-Time PCR machine from Applied Biosystems using the 7500 software v2.3. Running method for qPCR was including a standard protocol consisted of holding stage at 50°C for 20 seconds and a denaturing step at 95°C for 10 minutes, followed by 40 cycles of denaturing at 95°C for 15 seconds and an extension step at 60°C for 1 min. Gene expression was normalized to expression *ACTN2*, which is present in all muscle fiber types. Results are expressed as fold change compared to expression of the gene in quadriceps muscles.

### **Immunofluorescence**

Differentiated human myotubes grown on a glass coverslip coated with laminin were fixed with 4% paraformaldehyde (made in Phosphate Buffered Saline, PBS), permeabilized with 1% Triton in PBS for 20 min and processed as previously described (Treves, Vukcevic et al. 2011). The following antibodies were used: mouse anti-RyR1 (Thermo Scientific; MA3-925), goat anti- $Ca_v1.1$  (Santa Cruz; sc-8160), rabbit anti- $Ca_v1.2$  (Santa Cruz, sc-25686), AlexaFluor 488 conjugated-chicken anti-rabbit, AlexaFluor 555 conjugated-donkey anti-goat IgG (Life Technologies, Ltd) and AlexaFluor 647 conjugated-goat anti-mouse IgG (Life Technologies, Ltd). Cells were stained with 4',6-diamidino-2-

phenylindole (DAPI) (Life Technologies, Ltd) to visualize nuclei and observed using a Nikon A1R confocal microscope with a CFI Apo TIRF 100X (1.49 N.A.) objective.

### **Electrophoresis and Immunoblotting**

The total sarcoplasmic reticulum fraction was isolated from flash frozen muscle samples (human *orbicularis oculi*, EOM, quadriceps muscles and mouse heart) as previously described (Anderson, Treves et al. 2003) and stored in liquid nitrogen. The protein concentration was determined using the Protein Assay Kit II (Bio-Rad Laboratories) and BSA as a standard. SDS-PAGE, protein transfer on to nitrocellulose membranes and immunostaining were performed as previously described (Anderson, Treves et al. 2003). The following primary antibodies were used: mouse anti-RyR1 (Thermo Scientific, MA3-925), goat anti-Ca<sub>v</sub>1.1 (Santa Cruz sc-8160), rabbit anti-Ca<sub>v</sub>1.2 (Santa Cruz, sc-25686) rabbit anti-calsequestrin-1 (Sigma, C-0743), goat anti-SERCA1 (Santa Cruz, sc-8093) and mouse anti-sarcalumenin (Thermo Scientific, MA3-932) anti-dystrophin (Abcam, ab-7164), anti-utrophin (Santa Cruz, sc-15377) and mouse anti-myosin heavy chain (Millipore, 05-716). Secondary peroxidase conjugates were protein G-peroxidase (Sigma, P8170) and peroxidase-conjugated goat anti-mouse IgG (Sigma, A2304). The immunopositive bands were visualized by chemiluminescence using the Super Signal West Dura kit (Thermo Scientific) or the Chemiluminescence kit from Roche.

For Myosin Heavy Chain, gels were performed as described by Talmadge and Roy (Talmadge and Roy 1993) except that 30 µg total protein extracts were separated and the final acrylamide concentration was 6.5%. Gels were stained with Coomassie Brilliant Blue.

### **Statistical analysis**

Statistical analysis was performed using the Student's t-test for two populations. Values were considered significant when  $P < 0.05$ . When more than two groups were compared, analysis was performed by the ANOVA test followed by the Bonferroni post hoc test, using the GraphPad Prism 4.0 software. The Origin Pro 8.6 software was used for generating dose-response curves.

## RESULTS

### Gene and protein expression levels in human orbicularis oculi, EOM and quadriceps muscles

The expression levels of the major gene products involved in skeletal ECC is shown in figure 1A; the values obtained from *orbicularis oculi* were compared to those obtained from quadriceps of healthy donors. The latter muscles were used as reference and the expression level of different genes therein was set to 1. The results show the mean ( $\pm$ SEM) expression level of genes from five pooled biopsy samples normalized to *ACTN2*. The expression of *RYR1* and *SERCA1* transcripts was slightly elevated (approximately 2 fold; \* $P < 0.05$  Student's *t* test), as was that of *RYR3* and *CACNA1C* (5 and 10 fold, respectively; \*\*\* $P < 0.0001$  Student's *t* test) while *CACNA1S* expression was similar in *orbicularis oculi* and quadriceps muscles. Interestingly, the expression levels of *UTRN* and *DMD* showed  $\sim$  a 13 and 16-fold increase, respectively compared to quadriceps muscles (\*\*\* $P < 0.0001$  Student's *t* test). Although it was reported that *MYH13* isoform is exclusively expressed in EOM (Wieczorek, Periasamy et al. 1985), we also found that it is expressed in *orbicularis oculi* (Fig. 1B). *JP45* levels remained unchanged.

Total sarcoplasmic reticulum fractions were prepared and probed with antibodies against the major skeletal ECC proteins as well as  $Ca_v1.2$ ; the intensities of the immunoreactive bands were normalized to sarcalumenin content and are expressed as % expression of that of quadriceps muscles. Surprisingly, at the protein level the content of RyR1,  $Ca_v1.1$ , SERCA1, and CASQ1 were not changed between *orbicularis oculi* and quadriceps (Fig. 1C). We chose to normalize to SRL content and not to SERCA1 or calsequestrin 1, since by qPCR both SERCA1 and CSQ1 transcripts were significantly increased in *orbicularis oculi*.  $Ca_v1.2$ , the cardiac isoform of the DHPR could not be detected in western blots of *orbicularis oculi* and quadriceps, but it is clearly present in human EOM and mouse heart which served as positive control (Fig. 1D). Utrophin was highly expressed in both EOM and *orbicularis oculi* but less so in quadriceps (4-fold in OO vs QU \* $P < 0.05$ ), while the opposite was true for dystrophin (OO expressed approximately 50% compared to QU \* $P < 0.05$ ) (Fig. 1E).

## Ca<sup>2+</sup> homeostasis in human myotubes derived from *orbicularis oculi*, EOM and quadriceps

Since in a previous study we showed that primary cultures of myotubes explanted from human EOM muscle biopsies had different Ca<sup>2+</sup> handling properties, in the next series of experiments we compared Ca<sup>2+</sup> homeostasis in myotubes derived from the three types of muscles. In the first set of experiments cells were perfused with Krebs-Ringer containing 100 μM La<sup>3+</sup> to prevent influx of extracellular Ca<sup>2+</sup> and to ensure that the measurements represent skeletal ECC. As shown the KCl-induced Ca<sup>2+</sup> release was not different in *orbicularis oculi*-derived myotubes compared to quadriceps-derived myotubes (Fig. 2A). Similar results were reported for EOM (Sekulic-Jablanovic, Palmowski-Wolfe et al. 2015) and the curves are not shown in the figure for simplicity. The 4-cmc induced Ca<sup>2+</sup> release curve was also similar between *orbicularis oculi*- and quadriceps-derived myotubes (Fig. 2B). There were small differences in the resting [Ca<sup>2+</sup>]<sub>i</sub> in the three populations of myotubes while the size of the intracellular Ca<sup>2+</sup> stores of *orbicularis oculi*-derived myotubes were similar to those of quadriceps -derived myotubes, but significantly lower than those of EOM-derived myotubes (Fig. 2C and D; Student's *t* test \*\*\*P<0.0001).

We next investigated excitation-coupled Ca<sup>2+</sup> entry (ECCE), the process by which membrane depolarisation activates Ca<sup>2+</sup> influx through the dihydropyridine receptor (Bannister, Pessah et al. 2009). The top panels of figure 3A show pseudocoloured fluo-4 fluorescent changes in a representative myotube pre-treated with 50 μM ryanodine and stimulated with 60 mM KCl; the pre-treatment with high concentrations of ryanodine is necessary to block Ca<sup>2+</sup> release through RyR, ensuring that the change in fluo-4 fluorescence is not due to Ca<sup>2+</sup> release from the SR, but rather from Ca<sup>2+</sup> influx through the dihydropyridine receptor. Figure 3B shows a representative Ca<sup>2+</sup> influx trace initiated by the application of 60 mM KCl in *orbicularis oculi*-derived myotubes (\_\_\_\_), quadriceps-derived myotubes (-.-.-) and EOM-derived myotubes (.....). Figure 3C summarizes the results confirming that ECCE in *orbicularis oculi* myotubes is not significantly different from quadriceps myotubes, but almost 3 fold lower compared to EOM derived myotubes.

The difference in Ca<sup>2+</sup> influx between EOM and *orbicularis oculi* muscles most likely reflects the differential expression of Ca<sub>v</sub> isoforms in these groups of muscles. Figure 4 (top panels) shows the subcellular distribution of Ca<sub>v</sub>1.1 and RyR1 in *orbicularis oculi* myotubes; as seen the distribution of Ca<sub>v</sub>1.1 (panel A, green) and RyR1 (panel B, red) is

punctuated and unstructured, within an intracellular membrane compartment. Though they lack a mature organization, RyR1 and Ca<sub>v</sub>1.1 co-localize within the myotube (Fig. 4C). A similar subcellular punctuated distribution of Ca<sub>v</sub>1.1 (Fig. 4E) and RyR1 (Fig. 4F) is found in EOM myotubes however, there are major differences in the expression and distribution of Ca<sub>v</sub>1.2, that is, this isoform is exclusively distributed on the plasma membrane of EOM-derived myotubes (Fig. 4H) and could not be detected in *orbicularis oculi* myotubes (Fig. 4D).

## DISCUSSION

In the present study we investigated the biochemical and physiological characteristics of *orbicularis oculi* muscles a group of facial muscles that are selectively spared or involved in different neuromuscular disorders. As far as the expression of proteins involved in ECC is concerned, it appears that *orbicularis oculi* muscles are closer to quadriceps than to EOM. Indeed, the content of skeletal muscle sarcoplasmic reticulum proteins was similar between quadriceps and *orbicularis oculi* muscles and differed from that of EOM, as only the latter express proteins characteristic of both cardiac and skeletal muscle ECC (Sekulic-Jablanovic, Palmowski-Wolfe et al. 2015). Surprisingly however, the expression of transcripts did not always match the actual protein content, highlighting the importance of validating arrays or qPCR experiments whenever possible. This was particularly relevant for the difference between the expression of Ca<sub>v</sub>1.2 and dystrophin whose transcripts were increased >8-10 fold in *orbicularis oculi*, but at the protein level they were barely detectable. The reason for this discrepancy is at present unclear, but agreement between mRNA and protein content occurs only approximately 40% of the time and is influenced by different factors, including mRNA and protein stability, presence of microRNAs, posttranscriptional modifications, with the key role in determining protein abundance being played at the level of translation (Tian, Stepaniants et al. 2004, Vogel, Abreu Rde et al. 2010, Schwanhausser, Busse et al. 2011). A limited overlap in genomic and proteomic data was also reported by Khanna et al. while profiling EOM and leg muscles (Khanna, Merriam et al. 2003).

From a point of view of calcium homeostasis it appears that *orbicularis oculi* muscles are closer to quadriceps than to EOM, since the Ca<sup>2+</sup>-release dose response curves, the resting [Ca<sup>2+</sup>], and ionomycin/thapsigargin sensitive intracellular stores, in myotubes derived from the two muscle types were functionally undistinguishable and were clearly different from EOM-derived myotubes. The latter have significantly larger ionomycin/thapsigargin sensitive intracellular stores, express Ca<sub>v</sub>1.2 and exhibit a 3- fold

larger ECCE. One of the physiological characteristics of EOM muscles is that they are fatigue resistant (Fuchs and Binder 1983) and this may be functionally related to the high levels of expression of  $Ca_v1.2$  and consequent large  $Ca^{2+}$  influx. The  $Ca^{2+}$  influx may be used as a means (i) to activate ECC more rapidly by enhancing  $Ca^{2+}$  induced  $Ca^{2+}$  release, or (ii) to rapidly replenish intracellular stores. ECCE is less pronounced in myotubes derived from other skeletal muscles, most likely because they lack the cardiac isoform of the  $\alpha 1$  DHPR subunit.

Though *orbicularis oculi* express a typical skeletal muscle ECC, they also show similarities with EOM in that they express MyHC13 and high levels of RYR3. In humans, *Orbicularis oculi* are composed of 90% type II fibers and 10% type I fibers (Wirtschafter, Lander et al. 1994, Campbell, Williams et al. 1999) but our results show that they also express MyH13. In a study on levator palpebrae and retractor bulbi muscles from different species, it was shown that the latter muscles also express MyHC13 and that this is probably responsible for their rapid contracture times (<10 msec), in fact limb muscles do not express the superfast myosin isoforms and their contracture time is about 5 times longer (Lucas and Hoh 1997). As far as RYR3 expression is concerned, our results are enigmatic since in general RYR3 transcripts are expressed at low levels, if at all, in adult skeletal muscle (Martin, Chapman et al. 1998) and the role of RyR3 is unclear. RYR3KO mice are viable, their muscles show no obvious physiological differences compared to their wild type littermates including no changes in electrically induced  $Ca^{2+}$  release and contractile properties of adult muscle fibers, though skeletal muscles from neonatal RYR3 KO mice show decreased tension development (Takeshima, Ikemoto et al. 1996). Although for the time being the function of RyR3s is speculative, it is possible that these channels act as amplifiers of the  $Ca^{2+}$  signals; compatibly, RYR3KO mice were reported to have a mild cognitive impairment when tested on a water maze (Balschun, Wolfer et al. 1999), but retrospectively, this may have also been related to a visual impairment. Studies aimed at understanding the role of RyR3 in EOM are currently under way.

Our results concerning the expression of utrophin are interesting and most likely explain why in patients with Duchenne muscular dystrophy ocular and facial muscles are spared. Furthermore the observation that EOM are spared in Duchenne muscular dystrophy even though they exhibit a large  $Ca^{2+}$  influx, provides strong evidence that controlled  $Ca^{2+}$  influx *per se*, is not deleterious to skeletal muscles as recently proposed (Millay, Goonasekera et al. 2009), but is actually a physiological mechanism used by some skeletal muscles.

Utrophin and dystrophin share considerable sequence and structural homology (Tinsley, Blake et al. 1992, Winder, Gibson et al. 1995) and utrophin can associate with the dystrophin associated complex serving as a link between actin and the extracellular matrix (Matsumura, Ervasti et al. 1992). In mdx mice it is believed that utrophin compensates for the lack of dystrophin (Wakefield, Tinsley et al. 2000). Based on our results and on the fact that mdx knocked out also for utrophin show EOM involvement (Baker, Kearney et al. 2006), it appears that utrophin can functionally compensate *in vivo* for the lack of dystrophin, supporting the current strategies aimed at modulating utrophin expression in the therapy for Duchenne muscular dystrophy (Perkins and Davies 2002, Chakkalakal, Thompson et al. 2005, Guiraud, Squire et al. 2015).

Taken together these studies show that subspecialization of skeletal muscles occurs through multiple factors; while it is true that muscle innervation plays a prominent role, the distribution of a specific muscle within a niche devoted to a precise physiological function is also important. Indeed the term muscle allotype was proposed to describe the different capacities of myogenic cells of different lineages to express a different subset of myofibrillar genes. Since EOM, *Orbicularis oculi* and levator palpebrae (and the retractor bulbi which is present in some mammals but not in humans) are derived from cells from different lineage than those giving rise to limb muscles, their myogenic precursors must be programmed to express different subsets of proteins. The present study substantiates the validity of the muscle allotype hypothesis since we show that satellite cells derived from different muscles are primed and will follow the developmental characteristics of their muscle of origin, a property that can be exploited in laboratories devoted to tissue engineering.

## **AUTHOR CONTRIBUTION**

Marijana Sekulic-Jablanovic performed the experiments, analysed the data and drafted the article. Anja Palmowski-Wolfe and David Goldblum performed surgeries, provided the biopsies and critically revised the paper for important intellectual content. Francesco Zorzato was responsible for conception and design of the experiments, interpretation of data and critically revised the paper for important intellectual content. Susan Treves was responsible for conception and design of the experiments, collection, analysis and interpretation of data and drafted the article.

## **ACKNOWLEDGEMENTS**

We gratefully acknowledge the technical support of Anne-Sylvie Monnet. This work was supported by the Swiss National Science Foundation (SNF grant number 31003A-146198) and by the Department of Anesthesia Basel University Hospital.

## FIGURE LEGENDS

**Figure 1: Expression of major excitation-contraction coupling transcripts and proteins in human *orbicularis oculi* muscle biopsies.** (A) Gene expression was carried out by qPCR as described in the Materials and Methods section. Each reaction was carried out in triplicate, in pooled muscle samples from 5 biopsies from different individuals. Expression levels were normalized to *ACTN2* expression. Results are expressed as mean fold change of transcripts in *orbicularis oculi* compared to quadriceps, the latter was set as 1. Results were analyzed using the Student's *t*-test (\* $p < 0.05$ ; \*\*\* $P < 0.0001$ ). (B) *MYH13* gene expression was carried out by qPCR as described in Materials and Methods section. Each reaction was carried out in triplicate, in pooled muscle samples from 5 biopsies from different individuals. Expression levels were normalized to *ACTN2* expression. Results are expressed as mean fold change of transcripts in *orbicularis oculi* compared to quadriceps, the latter were set as 1. Results were analyzed using the Student's *t*-test (\*\*\* $p < 0.0001$ ). Insert shows MyHC protein expression in EOM and *orbicularis oculi* muscle homogenates; 10 and 30  $\mu\text{g}$  protein were loaded per lane, respectively. Gels and conditions were as described in the Materials and Methods section. (C) Western blot analysis of total sarcoplasmic reticulum proteins in human *orbicularis oculi* and quadriceps muscles. Thirty micrograms of protein were loaded per lane and separated on 6% SDS-PAGE or 10% SDS-PAGE. Blots were probed with the indicated antibodies. Bar histograms represent the mean ( $\pm$  SEM) band intensity normalized to sarcalumenin content. (D) Western blot of human quadriceps, EOM, *orbicularis oculi* and mouse heart (positive control) total sarcoplasmic reticulum proteins, probed with  $\text{Ca}_v1.2$  antibody. Thirty micrograms of protein was loaded per lane and separated on 6% SDS-PAGE. (E) Western blot of total muscle extracts; 30  $\mu\text{g}$  of protein were loaded per lane, separated on 6% SDS-PAGE and probed with anti-utrophin (top) and anti-dystrophin (bottom) antibodies. Bar histograms represent the mean ( $\pm$  SEM) band intensity normalized to MyHC content (\*  $P < 0.05$  Student's *t* test).

**Figure 2: Calcium homeostasis of *orbicularis oculi*-derived myotubes compared to quadriceps and EOM muscle-derived myotubes.** Myotubes were loaded with 5  $\mu\text{M}$  fura-2 and perfused with Krebs–Ringer medium containing 2 mM  $\text{CaCl}_2$ . For KCl- and 4-cmc induced  $\text{Ca}^{2+}$  release, individual cells were perfused with Krebs–Ringer plus 100  $\mu\text{M}$   $\text{La}^{3+}$  and the indicated concentration of agonist was applied using a microperfusion system. (A) KCl dose response curve (B) 4-cmc dose response curve- *Orbicularis oculi*-derived myotubes filled circles, continuous line and quadriceps derived myotubes empty circles, dotted line. Curves show the changes in peak calcium, expressed as  $[\text{Ca}^{2+}]$  in nM. Each point

represents the mean ( $\pm$ SEM) of minimum 5-12 different cells. **(C)** Mean ( $\pm$ SEM) resting  $[Ca^{2+}]$ . \* $P < 0.05$ ; \*\* $P < 0.001$ . **(D)** Total amount of  $Ca^{2+}$  in the sarcoplasmic reticulum. The total amount of rapidly releasable  $Ca^{2+}$  in the stores was determined by calculating the area under the curve of the transient induced by the application of 1  $\mu$ M ionomycin, plus 1  $\mu$ M thapsigargin in Krebs-Ringer containing 0.5 mM EGTA. Values represent the mean ( $\pm$  SEM) calculated area under the curve. Student's *t* test \*\*\* $p < 0.0001$ . For quadriceps-derived myotubes cells from 6 donors were measured, for *orbicularis oculi*-derived myotubes cells from 5 donors and for EOM-derived myotubes cells from 4 donors.

**Figure 3: Depolarization-induced  $Ca^{2+}$  influx in *orbicularis oculi*, EOM and quadriceps derived myotubes.**  $Ca^{2+}$  influx induced by the addition of 60 mM KCl was monitored using a TIRF microscope in myotubes pre-incubated with 50  $\mu$ M ryanodine to block RyR1 mediated  $Ca^{2+}$  release and loaded with 5  $\mu$ M fluo-4. **(A)** Top panels, pseudocolored ratiometric images (peak fluorescence after addition of KCl/resting fluorescence) of fluo-4 fluorescence changes after application of 60 KCl to *orbicularis oculi*-derived myotubes (**A1** EpiSRIC image, **A2-5** pseudocolored ratiometric images at 2, 5, 11 and 20 sec after the addition of KCl). **(B)** Representative excitation-coupled  $Ca^{2+}$  entry (ECCE) trace showing changes in fluo-4 fluorescence in a EOM-derived myotube ( . . . . ), quadriceps derived myotube ( . \_ . \_ ) and *orbicularis oculi* ( \_\_\_\_\_ ). **(C)** Mean ( $\pm$ SEM) peak increase of fluo-4 fluorescence induced by 60 mM KCl in human *orbicularis oculi*-derived myotubes (white bar), EOM derived-myotubes (gray bar) compared quadriceps-derived myotubes (black bar). Experiments were performed on cells obtained from at least 4 different biopsies and results were averaged. Statistical analysis was performed using the ANOVA test; \*\*\*  $P < 0.0001$ .

**Figure 4: Cellular localization of RyR1 and  $Ca_v1.1$  in differentiated *orbicularis oculi* - derived myotubes.** Human myotubes were visualized with a Nikon A1R confocal microscope equipped with a CFI Apo TIRF 100X objective (1.49 N.A.) and stained as described in the Materials and Methods section. Top panels *orbicularis oculi*, bottom panels EOM. Panels **A** and **E** anti- $Ca_v1.1$  (green), **B** and **F** anti-RyR1 (red), **C** and **G**, merged image of anti-RyR1, anti- $Ca_v1.1$  and DAPI (blue); orange pixels show co-localization between RyR1 and  $Ca_v1.1$ . Panels **D** and **H**, anti- $Ca_v1.2$  (green). Bar indicates 20  $\mu$ m.

## **2.2 Ryanodine receptors 1 and 3 – functional consequences of the mutations in human *RYR1* or the absence of *RYR3* in mice**

### **2.2.1 Introduction**

Ryanodine receptor 1 plays a crucial role in the process of the excitation contraction coupling in skeletal muscle. According to our study on human EOM, the expression of this receptor is decreased in EOM compared to that of human leg muscles. We were intrigued by this finding, as EOMs belong to the group of specialized skeletal muscles. Previous investigations in patients with recessive mutations in *RYR1* where one allele carries missense mutation and other stop mutation, indicated the presence of the weakness of the EOM muscles, known as ophthalmoplegia. In those patients muscle biopsies show a decrease in the content of the RyR1 protein [171]. For the purpose of investigating the effects of mutations found in these patients, we subcloned human *RYR1* cDNA into a mammalian bicistronic vector and used it for the insertion of specific mutations.

As mentioned in the previous sections RyR3 does not directly participate in ECC, as mature muscles express either very little or no RyR3 and still show normal excitation-contraction coupling and *RYR3* KO mice show no muscle impairment, no changes in muscle development and no alteration of other studied physiological parameters, except for a reported cognitive impairment [172].

In light of our findings on the low levels of RyR1 expression in EOM together with the low levels of skeletal alpha 1s of the DHPR and the presence of the cardiac alpha 1c isoform, we were prompted to investigate the EOM function in the *RYR3* KO mice in fact we hypothesize that this animal model has an impairment of EOM function and this was not investigated in previous studies.

## 2.2.2 Subcloning and introducing the mutations in human *RYR1*

In order to better understand the consequences of *RYR1* mutations, the human *RYR1* mRNA from healthy donor was used as template for cDNA synthesis which was further subcloned and finally used to establish a stably transfected cell culture of HEK 293 expressing RyR1. Furthermore RyR1-vector construct was used for introducing specific mutations found in patients.

### Assembling the RyR1-vector construct

*RYR1* cDNA was synthesized using mRNA isolated from human skeletal muscle as a template (transcript variant 2, NCBI Reference Sequence: NM\_001042723.1). When compared with the NCBI nucleotide database entry, six nucleotide changes that do not affect the amino acid sequence of the RyR1 protein were detected by sequencing. These were: c.724A>G, c.1207T>C, c.1798G>A, c.2416 C>T, c.3073G>A and c.9187C>T.

The full length *RYR1* cDNA was assembled through a series of subcloning steps in which fragments of different sizes (from 600bp-2629bp) were amplified by insertion in the pBSK (-) vector, followed by ligation and joining one insert at a time to obtain the full length construct (Fig. 17). Each fragment was checked by direct sequencing before being ligated to the next clone. The final complete *RYR1* cDNA sequence inserted in pBSK(-) was confirmed to be from the first ATG start codon to the stop codon (positions 131-15234 of the *RYR1* sequence). The full length *RYR1* cDNA was inserted in pIRES-DsRed vector in order to achieve transfection and expression in mammalian cells.

**Figure 17: *RYR1* cDNA subcloning scheme.** In the scheme are represented the restriction sites chosen to break the total cDNA into smaller clones to be used in a second phase of getting the full length cDNA.

3`untranslated region of *RYR1* was first inserted in pBSK(-) vector through digestion with HindIII/XbaI and this new construct was digested with SacI/SalI in order to transfer 3`UTR in pIRES-DsRed vector. In the final step, *RYR1* insert was cut out from the pBSK(-) with SpeI/XbaI and inserted in XbaI digested 3`UTR in pIRES-DsRed construct (Fig. 18).

**Figure 18: Final assembling of *RYR1* insert with its 3`UTR fragment in pIRES-DsRed vector.**

### Stable transfection

HEK293 were stably transfected with the *RYR1* cDNA construct outlined above in order to ascertain that the appropriate recombinant protein was obtained. HEK293 cells were chosen for transfection because they do not express endogenous RyR1. The stably transfected clones D2 and A5 were observed for the DsRed fluorescence and as shown in figure 19, all the cells were positive for the DsRed signal. Transfected cells were collected and the microsomal fraction was prepared. As can be seen in figure 20, a high molecular weight immunoreactive band was present in the microsomes of transfected cells. The size of the immunoreactive band matched that of RyR1 present in rabbit terminal cisternae.

**Figure 19. DsRed fluorescence present in the stably transfected HEK293 clones.** Cells from clones A5 and D2 grown on laminin coated glass coverslips and observed for the DsRed fluorescence.

**Figure 20: Western blot of microsomes from transfected Hek293 cells.** (clones A5 and D2) 40μg and 80 μg protein were loaded per lane for each clone and separated on a 5% SDS-PAG. The blot was incubated with 0.5 μg/ml mAb 34C anti-RyR1 followed by anti–mouse peroxidase and the reaction was visualized by chemiluminescence.

The lanes on the left (positive control) were loaded with 4 and 2 μg rabbit skeletal muscle terminal cisternae and the arrow indicates the immunoreactive band corresponding to the RyR1 protomer.

Stably transfected cells from clone A5 were grown on a glass coverslip and fixed with 4% paraformaldehyde, permeabilized with 1% Triton in PBS for 20 min and stained with the mouse anti-RyR1 antibody. The staining was positive for the presence of the RyR1 protein in the cells as well as previously shown DsRed fluorescence (Fig. 21).

**Figure 21: Cellular localization of RyR1 and DsRed.** Merged image of cells stained with anti-RyR1 (green), nuclear counterstain DAPI (blue) and expressed DsRed protein fluorescence (red). Visualized with a Nikon A1R confocal microscope equipped with a CFI Apo TIRF 100X objective (1.49N.A.)

### **Ca<sup>2+</sup> measurements**

Clones were further tested for RyR1 function by monitoring calcium changes after stimulation with the RyR1 agonist 4-chloro-m-cresol (600 $\mu$ M) and caffeine (10mM). Positive clones were expanded and allowed to grow on glass coverslips; when enough cells were present, they were loaded with the ratiometric Ca<sup>2+</sup> indicator fura-2 and changes in fluorescence were monitored. Figure 22 shows the results of a representative experiment. Traces A and B are showing that transfected HEK293 respond to the addition of 10 mM caffeine and 600 $\mu$ M 4-cmc respectively. Panel C shows the pseudo colored ratiometric changes in fura-2 fluorescence elicited by the addition of 600 $\mu$ M 4-cmc in the latter cells.

**Figure 22: HEK293 cells transfected with human RYR1 respond to caffeine and 4-cmc addition.** Cells from selected clones were grown on glass coverslips, loaded with 10µM fura-2  $\text{Ca}^{2+}$  indicator and stimulated with (A) 10 mM caffeine and (B) 600µM 4-cmc in Krebs Ringer. (C) photographs of cells B showing 3 time points during caffeine stimulation. The trace shown in panel B was obtained from the cell indicated by the arrow in trace C.

After the stability of the expression of RyR1 in previously described clones was confirmed, the next step was to introduce mutations into RyR1 receptor sequence and test for the functional and protein expression changes. A premature stop mutation similar to one found in patients  $c.2367C>A$  was introduced into *RYR1* vector and using the electroporation protocol mutated cDNA was introduced into FDB. Briefly, cDNA from nucleotide 131 to 2367 was amplified by PCR and subcloned into the pIRES-DsRed vector (Clontech) into which the 3'UTR sequence of RyR1 (from nucleotide 15235-15376) had previously been inserted. The following primers were used for *RYR1*<sub>TRUNC</sub> subcloning: F 5'- GACCT CGA GGT CGA CGG TAT CGA TAA-3' and R 5'-GGATC TAG AAC GCT GAG GTC CAG TCA G -3'. All sequences were verified by Sanger sequencing.

Mouse FDB were then electroporated with the wild type or truncated *RYR1*; after one week FDB fibers were isolated and proteins were probed for the presence of the ubiquitin as a signal for degradation. As can be seen in figure 23A the band with truncated RyR1 protein is heavily marked with anti-ubiquitin antibody (Millipore 04-363), while at the same time the mRNA levels of truncated *RYR1* are highly increased compared to the control levels detected from the isolated FDB fibers of the other leg, indicating that electroporation was efficient (Fig. 23B), but the translated protein is being degraded.

**Figure 23: Increase in ubiquitination of the truncated RyR1 protein.** (A) Western blot of the total homogenate from the isolated FDB fibers, from control leg and electroporated one, probed for anti-ubiquitin antibody and normalized to MyHC content. (B) Relative expression of truncated RYR1 in isolated transfected fibers compared to control fibers.

### 2.2.3 Extraocular muscle properties in RyR3 knockout mice

Considering that we found *RYR3* to be highly expressed in human EOM it was equally interesting to test *RYR3* levels in mouse EOM. As can be seen in figure 23, the pattern of *RYR1*, *CACNA1S*, and *CASQ2* expression was different in mouse EOM compared to human EOM, but the *RYR3* transcript levels were similarly increased, up to 100 fold compared to FDB fibers. This led us to investigate the function of the extraocular muscles in the *RYR3* knockout mice.

**Figure 23: Expression of excitation-contraction coupling transcripts in human (A) and mouse (B) extraocular muscle biopsies.** Gene expression was quantified by qPCR. Each reaction was carried out in triplicate, in pooled muscle samples from 4-5 biopsies from different individuals. Expression levels were normalized to *ACTN2* expression. Results are expressed as mean fold change of transcripts in EOM compared to human quadriceps muscles and to mouse FDB fibers, the latter were set as 1. Results were analyzed using the Student's t-test (\*\*p<0.0001, \*\*p<0.001, \*p<0.01).

For the preliminary functional test, we chose to investigate the optokinetic reflex and measure visual acuity (clarity of vision), using the OptoMotry© system. Image stabilization is predominantly mediated by two types of oculomotor responses: the optokinetic reflex (OKR; also called optokinetic nystagmus or OKN) and the vestibulo-ocular reflex (VOR). The OKR is induced when the entire visual scene drifts across the retina, eliciting eye rotation in the same direction and at a velocity that minimizes the motion of the image on the retina. The VOR is an analogous response to head movement, with input coming from the vestibular system rather than the retina. Normally, the OKR and VOR work together to ensure image stabilization on the retina. Both the OKR and the VOR are controlled by subcortical circuits: the OKR is controlled by neurons in the retina, diencephalon and midbrain (the accessory optic system), pons, and dorsal medulla, and the VOR is controlled by neurons in the labyrinth of the inner ear, midbrain, pons, dorsal medulla, and cerebellum [173].

OptoMotry© is used for the rapid screening of functional vision using the optokinetic tracking/reflex (OKT/R) response. Spatial frequency thresholds can be measured by systematically increasing the spatial frequency of the grating at 100% contrast until animals no longer track. A contrast sensitivity function can be generated by identifying the minimum contrast that generates tracking, over a range of spatial frequencies. Single thresholds can be obtained in a few minutes in animals with no previous exposure to the task, and measurements can be repeated regularly. Rodents stand on an elevated platform in the epicenter of an arena surrounded by computer monitors, and a camera images the behavior of the animal from above (Fig. 24). A cylinder comprised of a sine wave grating is drawn in 3D coordinate space and rotates around the animal. Animals track the grating with reflexive head and neck movements (Fig. 25). A cursor placed on the forehead centers in real time the rotation of the cylinder at the animal's viewing position, thereby "clamping" the effective spatial frequency of the grating [174].

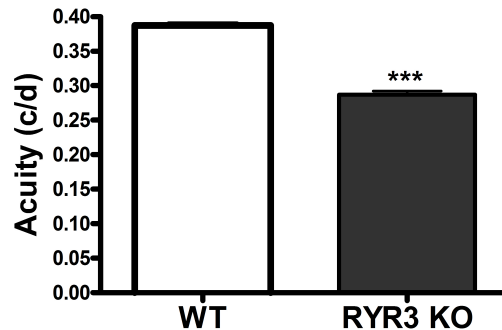

**Figure 24: Schematic representation of the optomotor testing apparatus. (A)** Side view. A mouse is placed on a platform positioned in the middle of an arena created by a quad-square of computer monitors. Sine wave gratings drawn on the screens are extended vertically with floor and ceiling mirrors. A video camera is used to monitor the animal's behavior from above. **(B)** Top view. The mouse is surrounded by 360° of gratings and is allowed to move freely on the platform [174].

**Figure 25: Virtual geometry and optomotor response. (A)** A virtual cylinder is projected in 3-D coordinate space on the monitors. The head of the mouse centers the rotation of the cylinder. **(B)** When the cylinder is rotated, the mouse tracks the drifting grating with head and neck movements. **(C)** A single-frame video camera image of a mouse tracking the cylinder grating. The four-line crosshair is positioned between the eyes of the mouse, and the coordinates are used to center the rotation of the cylinder [174].

According to the results obtained after the first tests, there is a significant difference ( $***p<0.0001$ ) in the visual acuity between *RYR3* KO mice and WT, in terms of poorer vision of the knockout mice (Fig. 26).

**Figure 26: Visual acuity test of *RYR3* KO mice.** OptoMotry© detection system. Unit for visual acuity used is c/d (cycle/degree). 10 WT and 10 *RYR3* KO mice tested in two independent measurements. Results were analyzed using the Student's t-test  $***p<0.0001$ .

This was a good starting point for the measurements of EOM muscle function. The next planned experiment was a water maze test, where the visual impairment of *RYR3* KO mice was further investigated. Visual acuity was tested using the visual platform version of the Morris Water maze. A round gray tank of 1,7m diameter filled to a height of 30cm with water at room temperature of  $23 \pm 1^\circ\text{C}$  was used. The water was made opaque by the addition of non-toxic white paint. A video-camera fastened above the center of the pool recorded the swimming patterns of the mice, using a video tracking system (Ethovision™ XT11, Noldus Information Technology, Wageningen, Netherlands). The water surface was virtually divided into four quadrants. A white, round platform with a diameter of 10 cm, was placed in one quadrant, at a distance of 50 cm from the border and 2 cm above the water surface. 4 entry zones are marked outside the pool. The room was illuminated at an intensity of  $<150$  Lux. Animals are transferred to the experimental room where they were given at least 72 h to acclimatize in 12 hourly light/dark cycles, the light being switched on at 6 am. Animals were provided with water and food ad libitum. On day 0, animals performed a habituation run, swimming for 60 sec in the water maze, after this period they were placed on the platform for 15 seconds. On day 1, animals were tested in a total of 4 trials with the platform at a fixed position, and varying each of the four entry zones. Test duration was 60

sec per run. If the animal did not find the platform after 60 sec, it was guided to it by hand and allowed to stay for 15 seconds. On day 2, tests were repeated in a similar way as day 1, except that the platform was moved in the opposite quadrant. Parameters that were evaluated are: swimming velocity, total distance moved and time to reach the platform. There was no difference in swimming velocity between two strains, which was good indicator that the swimming capacity is unchanged in *RYR3* KO and does not contribute to detected significantly higher time and distance to reach the platform (\* $p < 0.05$  and \*\* $p < 0.005$  respectively) (Fig. 27).

**Figure 27: Water maze results show visual impairment in *RYR3* KO mice.** The results are average per experimental group, per day. **(A)** Time spent to reach the platform; 10 mice were measured per strain and data from 4 different entry points are pooled. **(B)** Distance to reach the platform; 10 mice were measured per strain and data from 4 different entry points were pooled; \* $p < 0.05$ , \*\* $p < 0.005$ .

Functional and biochemical testing of the isolated EOM fibers will be also part of the characterization of the *RYR3* KO EOM phenotype. So far, I have isolated mouse WT EOM fibers, and by confocal microscopy showed that the  $Ca_v1.1$ , RyR1 proteins are distributed as in skeletal muscle fibers, but the cardiac isoform of DHPR  $Ca_v1.2$  was found to be expressed and localized only on the membrane of the fiber, as previously found in human EOM derived myotubes (Fig. 28).

**Figure 28: Cellular localization of RyR1, Cav1.1 and Cav1.2 in Mouse Extraocular muscle fiber.** Samples were stained as previously described. Fiber was visualized with a Nikon A1R confocal microscope equipped with a CFI Apo TIRF 100X objective (1.49 N.A.).

# CHAPTER 3: GENERAL CONCLUSION AND PERSPECTIVES

Extraocular muscles are affected in individuals carrying recessive *RYR1* mutations associated with multi-minicore disease, centronuclear myopathy and congenital fiber-type disproportion. Patients with severe congenital ophthalmoplegia and facial weakness in the setting of only mild skeletal myopathy harbor recessive mutations in *RYR1*, and are susceptible to malignant hyperthermia [175]. On the other hand, even within Malignant hyperthermia which is inherited in a dominant manner, there is a subgroup of patients which respond with masseter muscle rigidity - a severe, sustained contraction of the jaw muscle that may be observed after the administration of succinylcholine [176]. Our interest to investigate closer the properties of two muscle groups, the extraocular muscles and the facial orbicularis oculi muscles, led us to interesting discoveries. Finding that all major components of the skeletal excitation-contraction coupling in EOM were expressed at a lower levels was unexpected, as it is well known that EOM are one of the fastest muscles in the body. That was intriguing and made us question as to what additional signaling mechanism these muscles rely on. If it is not completely skeletal, might there be involvement of cardiac ECC components or some other factors? Indeed, the transcripts encoding RyR3, cardiac calsequestrin (CSQ2) and the  $\alpha 1$  subunit of the cardiac dihydropyridine receptor were highly expressed in EOM compared to leg muscle. Cardiac DHPR was localized exclusively on the membrane of the EOM-derived myotubes and this was the first time that this isoform was detected in skeletal muscles. What is the exact role of this receptor in EOM muscles and how it contributes to the EOM phenotype is yet to be discovered. One explanation could be the increased depolarization induced  $\text{Ca}^{2+}$  influx in EOM that we reported, as it is practically abolished after adding of 50 $\mu\text{M}$  nifedipine to myotubes incubated in ryanodine. To what extent this effect can be attributed to the presence of cardiac DHPR cannot be resolved based on the experiments as nifedipine blocks the L-type calcium channels and is not specific for one isoform.

After discovering the high expression levels of *RYR3* transcript, we were interested to know its role in EOM, since this isoform is highly expressed only during muscle development and in low levels in adult muscle tissues, such as the diaphragm and soleus. It seems that RyR3 is not involved in ECC directly, as mice lacking this receptor show subtle changes in ECC and it seems that RyR1 successfully compensates for the absence of RyR3. This effect does not necessarily reflect the lack of RyR3 involvement in muscle, but might be the consequence of already low content of RyR3. In addition, when both receptors RyR1 and RyR3 are absent, functional and structural impairment is even more pronounced and this indicates that when RyR1 is absent, RyR3 does show some effect on myofibrillar organization. The reported reduction in the caffeine response of the RyR3 KO mice indicates that RyR3 could play a role in the CICR mechanism. Despite the fact that in RyR3 KO mice ECC is normal, a reduced CICR response was present at high  $\text{Ca}^{2+}$  concentrations [116, 177]. According to the results we have so far on extraocular muscles from RyR3 KO mice, their optokinetic reflex seems to be impaired and the water maze test confirmed a visual impairment, since RyR3 KO mice failed to see the platform and this was translated in a longer time and distance to reach the platform, compared to WT mice. At the same time the velocity of the RyR3 KO mice was not different compared to WT, which excludes the possibility that the lower values in time and distance for RyR3 KO mice were due to general weaker muscle performance. Further testing would give some additional insights in the EOM muscle and muscle fiber function of these mice, as EOM are constantly active and require an exquisite calcium management. Further experiments on the RyR3 KO mice will be conducted and will be combined with the biochemical characterization and  $\text{Ca}^{2+}$  measurements on isolated EOM fibers.

We have found that orbicularis oculi muscles exhibit more similarities with LM than with EOM in terms of protein and mRNA levels of skeletal ECC components. On a protein level, they seem not to express the cardiac isoform of the DHPR which was instead found to be present in EOM and this was supported by the unchanged ECCE compared to LM-derived myotubes. In Duchenne muscular dystrophy EOM are spared from pathology. The same is confirmed in mdx mice models where EOM are spared; while at the same time accessory EOM (retractor bulbi and LPS) are affected. We have found that human OO express higher levels of both dystrophin and utrophin. The next step would be to investigate the protein levels of utrophin and dystrophin in both OO and EOM and to see if there are any differences between them.

The second part of this thesis refers to RyR1 low protein levels found in patients with recessive *RYR1* mutations. The human *RYR1* cDNA was subcloned into a mammalian vector and used for the insertion of specific mutations found in patients. We thus discovered that introduction of a premature stop codon causes protein degradation. Further investigations will combine the insertion of several different mutations found in patients and following the functional effect on Ca<sup>2+</sup> regulation, protein level expression and function in transfected cells. This investigation will hopefully clarify at least in part, what factors are involved in the pathophysiological mechanism of recessive *RYR1* mutations leading to disease and impaired muscle function.

# CURRICULUM VITAE

**Name:** Marijana  
**First name:** Sekulic  
**Birth Date/Place:** 19/08/1985, Novi Sad, (Serbia)

## Education:

Feb, 2012 – Feb, 2016 PhD studies /Cell Biology/: Perioperative Patient Safety group, Department of Biomedicine, University Hospital Basel, University of Basel

2009 Master Studies /Molecular Biology/ Faculty of Science, University of Novi Sad, Serbia

2004 - 2008 Undergraduate studies, four-year program /Molecular Biology/, Faculty of Science, University of Novi Sad, Serbia

2000 - 2004 High School: /Medical High School/, four-year program, Novi Sad, Serbia

## Publications:

- 1. Characterization of excitation-contraction coupling components in human extraocular muscles.** Sekulic-Jablanovic M., Palowski-Wolfe A., Zorzato F. and Treves S. *Biochemical Journal*, 2015 Feb 15; **466**(1):29-36. doi: 10.1042/BJ20140970.
- 2. Epigenetic changes as a common trigger of muscle weakness in congenital myopathies.** Rokach O, Sekulic-Jablanovic M, Voermans N, Wilmshurst J, Pillay K, Heytens L, Zhou H, Muntoni F, Gautel M, Nevo Y, Mitrani-Rosenbaum S, Attali R, Finotti A, Gambari R, Mosca B, Jungbluth H, Zorzato F, Treves S. *Hum Mol Genet.* 2015 Aug 15; **24**(16):4636-47. doi: 10.1093/hmg/ddv195. Epub 2015 May 27
